Automotive battery cable	60-1394-023

AC POWER CONVERTER/BATTERY CHARGER. To power sampler from 117VAC 50/60Hz line power or to recharge battery for use with standard speed pump samplers only. 60-1684-046

Same as above except for use with super-speed pump samplers. 60-1684-080

Same as above except for 214VAC 50/60Hz line power and for use with both standard and super-speed pump samplers. 60-1684-081

SUSPENSION HARNESS. A snap-on, all stainless steel harness allows fast manhole installation by suspension from a rung or other projection.

Suspension harness for samplers 60-1394-014

SUCTION LINES. Each suction line has a weighted, streamlined strainer to prevent debris from entering the sampler. ISCO lines are specially extruded from clear vinyl, free of phenolic compounds, or teflon.

Vinyl tubing is available in bulk quantities for occasions when replacing the line is easier than cleaning it. Line replacement between surveys also assures no possible cross-contamination which can complicate legal proceedings. Bulk line is sold without the strainer.

1/4" I.D. x 22' suction line with polypropylene strainer	60-1394-054
3/8" I.D. x 20' suction line with polypropylene strainer	60-1684-015
1/8" I.D. x 10' Teflon® suction line "Hypodermic" rubber coupling, without strainer	60-1681-146
Same except 20' length	60-1681-148
Weighted strainer only, 1/4" polypropylene body	60-1394-070

Weighted strainer, 3/8" all stainless steel	60-1684-110
Fishing tool to allow mounting above strainer on Teflon® tubing	60-2101-093
Bulk 1/4" I.D. vinyl tubing only, 100'	60-1680-055
Same, 500'	60-1680-056
Same, 1000'	60-1680-057
Bulk 3/8" I.D. vinyl tubing only, 100'	60-1680-058
Same, 500'	60-1680-059

LIQUID LEVEL SAMPLER ACTUATOR. This unit causes a dormant sampler to begin operation when the liquid level in a stream rises to some predetermined height. It consists of a small controller which attaches inside the sampler cover, and a 22' cable ending in a rainproof detector. This detector can be staked at any level in the stream bed and will initiate a preprogrammed sampling sequence when the stream rises to this height. A switch can be set to terminate sampling when the stream lowers below the detector, or to continue to run out the program. It cannot be used at the same time as the flow meter without special modification. Contact the factory for details on these applications.

Liquid level sampler actuator 60-1644-080

Liquid level sampler actuator

flow proportional sampling

All ISCO samplers are designed to collect samples on a timed basis or proportional to flow using input signals from an external flow meter. Electronically, ISCO samplers require a 12 VDC input pulse or an isolated contact closure of at least 25 milliseconds duration to cause a sample to be taken and/or to register a flow pulse.

Connection of an ISCO sampler to an ISCO flow meter is easily made with finished connect cables supplied with the flow meter or purchased separately in the case of the Model 1870. ISCO flow meters can then be programmed to send a pulse to the sampler for every 10, 100, or 1000 increments of flow. ISCO samplers Model 1680 and 2100 can then be programmed to multiply these signals from 1 to 999 times to give a wide range of sampling frequency. The Model 1580 can be programmed to multiply input signals from 1 to 9 times.

Certain non-ISCO flow meters that have an isolated contact closure of at least 25 milliseconds duration can be directly interfaced with ISCO samplers. This is accomplished by using either the connector without cable or the connector with 22' cable listed below. The connector or connector with 22' of cable is attached to the FLOW METER socket on the ISCO sampler control unit. The connector with 22' of cable ends in bare wires which must be connected to the non-ISCO flow meter by using the appropriate connector and clamp which should be available from the flow meter manufacturer, or the cable can be hard wired into the flow meter.

Non-ISCO flow meters that do not produce an isolated contact closure will require a special interface device to convert the output signal to a contact closure. Output signals from these flow meters are generally either a pulse duration proportional to flow, a pulse rate proportional to flow, or more commonly a current signal (e.g. 4-20ma) proportional to flow. Current signals may either be proportional to flow or proportional to the flow squared. In order to pace an ISCO sampler proportional to flow from one of these flow meters, a special interface device must be used.

All ISCO interface devices are custom designed for each application and therefore, a data sheet (Isco Form #526a) must be completed and returned with the order. These data sheets are available from ISCO or from an ISCO representative. Because these interface devices are custom built, please allow up to 6 weeks for delivery. All interface devices are supplied with a 6-ft. cable and appropriate connector for attachment to the ISCO sampler. Each unit is also supplied with a 3-ft. cable with one end bare for connection to the non-ISCO flow meter. Longer cables may be specified at extra cost. The interface closure is NEMA Type 4.

ISCO interface devices Types A and B get their power from the ISCO sampler. Interface device Type C can get its power from a 117 VAC power source or from the ISCO sampler. If 117 VAC power is desired, a regular 3-prong grounded socket must be available nearby. If it is desired to power the interface from the sampler, then a different Type C interface is required. The sampler may be powered from 117 VAC or 12 VDC.

If it is desired to pace more than one sampler from one interface device, additional outputs can be ordered on the interface at $25.00 each.

Connector only, without cable, for use with non-ISCO flow meters having an isolated contact closure proportional to flow	60-1683-080
Same with 22' cable terminating in bare wires	60-1394-077
Interface Device Type A (converts pulse duration flow meter output proportional to flow to pulse output occurring at settable flow intervals)	60-1784-007
Interface Device Type B (converts direct flow meter contact closure or pulse rate proportional to flow to pulse output occurring at settable flow intervals)	60-1784-026
Interface Device Type C (for 117VAC operation. Converts current signal proportional to flow (4-20ma) to 30 Volts, 50 ms pulse output occurring at settable flow intervals)	60-1784-011
Interface Device Type C, powered by sampler	60-1784-003
Interface device Type C (for 117 VAC operation. Converts current signal proportional to flow squared	60-1784-020

Chapter 61

ANALYTICAL ADVANCES AND PROCESS CONTROLS

INTRODUCTION

Environmental protection regulations requiring ever decreasing metal concentrations create the need for reliable and improved analytical techniques. Mine and mineral processing environments are often remote, and there are needs for simple, and where possible, less expensive rapid techniques for these analyses. These analyses are needed for reporting purposes, to prove that the operation is operating within the law, and to provide some warning that contaminant levels are approaching regulated limits in time to implement corrective measures.

In this respect, it is equally important that the sample be taken in a reproducible manner, and that it is representative. Further, it should be handled in such a way between drawing of the sample and the actual analysis that no misleading changes take place.

A second equally important use of analytical techniques is to control reagent additions in metallurgical processes and in effluent treatment systems. Sometimes the reagent used to remove a toxic contaminant may itself be toxic--for example, chlorine addition for cyanide destruction, or Na_2S addition for hexavalent chromium removal or to polish solutions after heavy metal removal.

By monitoring metallurgical processes, reagent additions can be controlled continuously to cater to changes in ore quality. Not only will this help reduce reagent costs and improve metallurgical efficiency, but the cost of removing excess reagents can be kept to a minimum.

During this investigation, important progress was observed in Canada in the development of almost completely automated water treatment plants. This requires reliable means of controlling such processes by using microprocessors.

This chapter mentions just a few of the useful items of analytical technique and process control that were encountered. No deliberate survey of the field was carried out, and no effort was made to make a complete survey.

CYANIDE ANALYSIS

Cyanide analysis techniques are discussed in Chapter 40 on Cyanide. Of particular importance are the following developments.

- "Free" Cyanide Analysis

  The ASTM "free" cyanide titration method does not quantitatively determine all free cyanide of environmental consequence such as copper and nickel cyanides.

  The method has been improved by E. I duPont de Nemours & Co. by adding a small aliquot of zinc dust which liberates cyanide from both copper and zinc cyanide complexes which then makes these cyanides quantitatively measurable by titration.

  The titration is precise down to around 1 ppm "free" CN. Iron cyanide is not measured by the technique.

  The method is being further developed and tested to find out if it is applicable to the potentiometric titration, specific ion electrode, and Hachmeter rapid colorimetric field method which should have a detection limit around 0.1 ppm.

  Addotopma; cuamode ,pmotpromg ,etjpds were discussed at a conference on "Cyanide and the Environment" held at the University of Arizona in Tucson in December, 1984.

  More information on the "Cyanide Conference" is available from:

MODIFIED FREE CYANIDE METHOD

Dear Hans:

As we discussed, here is the method we have recently released to cover weak-acid-dissociable cyanides. Proving the zinc cementation concept using the Hach Kit is in progress. If all goes well, Owen Mathre will report on this at Tucson.

Best regards,

F. W. DeVries

FWD:pag
Encls.

TECHNICAL INFORMATION

MODIFIED FREE* CYANIDE - FIELD TEST
TITRATION METHOD WITHOUT DISTILLATION

Principle

Gold and silver milling process streams generally contain complex iron cyanides, free sodium cyanide and a number of metal complexes that contain cyanide that is measured as weak acid dissociable (WAD) cyanide by generally accepted methodology. The cyanide is released from the WAD complexes by reaction with zinc dust in the presence of ammonia and sodium hydroxide. Sulfide, a common interference in determination of cyanide in mine process solutions and wastewater, is removed by reaction with lead carbonate to form lead sulfide which is filtered before the zinc treatment is started. There is also some evidence that some of the thiocyanate may be removed with the sulfide.

The released cyanide is finally measured by titration with silver nitrate.

[illegible]

Safety

1. Lead carbonate should be handled according to practices required for protection from acceptable exposure to the dust.

2. Zinc dust wet with alkaline solutions may be pyrophoric. Avoid letting air pass through the filter until it has been washed with water. Do not discard alkaline filter cake in containers or locations that contain combustible materials.

Apparatus

1. Buret, micrometer syringe type. The Hach Chemical digital titrator with standard solution supplied in plastic syringe cartridges has been used. The Gilmont digital pipet, "Teflon" piston, 2-mL size with a buret tip, has also been used with conventional standard 0.0200 N and 0.100 N silver nitrate solution.

2. Filter paper. Fast filtering paper is generally preferred. Medium speed filter paper should also be available if the fast filter paper does not remove all of the solids in the sulfide filtration.

3. Magnetic stirrer. These units are available from a laboratory supply house and may be powered with a battery powered tire pump. They will also run with ordinary laboratory air or water supplies.

4. Standard laboratory glassware. Graduated cylinder and pipets to measure samples, Erlenmeyer flasks or bottles to do the reactions and titrations in and a filter system (gravity or syringe operated pressure) for separation of solids (both lead sulfide and zinc are needed).

*Modified ~~free~~ cyanides include what are generally called "free cyanides" and "weak acid dissociable cyanides".

Reagents

1. Ammonia, ACS reagent.

2. Indicator, Deniges. Dissolve 10.0 g potassium iodide in 100-mL reagent ammonia solution. Use 2.0 mL for each 100 mL of solution to be titrated.

3. Lead carbonate, ACS reagent. It has been found that a 10% w/v solution of lead acetate can be used if the sulfide content is not too high. This reduces the possible exposure to dusts of lead salts during analysis. However, the excess reagent must be controlled more carefully.

4. Potassium iodide, ACS reagent. This is needed to make up the indicator solution.

5. Sodium hydroxide, 5 M. Dissolve 200 g sodium hydroxide in about 500 mL water. Dilute to one liter. Store in a plastic bottle.

6. Standard silver nitrate, 0.100 N and 0.0200 N. Prepare with dilute solution by diluting 20.0 mL of 0.100 N solution to 100 mL with deionized water.

   Alternately, the silver nitrate solution may be purchased in cartridges for the Hach digital titrator and used as supplied.

7. Zinc, dust. ACS reagent has been satisfactory. Granular zinc reacts too slowly and does not generally have enough surface area to be satisfactory for this procedure.

Procedure

Sample Preparation

1. Measure 50 mL solution into the reaction bottle or flask.

   If the sample is expected to contain less than 5 mg WAD cyanide/L, use 100 mL.

   If the sample is expected to contain more than 200 mg WAD cyanide/L, then use 10 mL of sample and add 15 mL deionized water to the reaction bottle.

2. Add about 0.1 g of lead carbonate to the sample and swirl vigorously to react the sulfide with the lead. If the black lead sulfide forms, then add 1 g more and swirl vigorously to react the sulfide. Filter through medium filter paper into another reaction bottle. Wash the filter with about 10 mL of water. This should have removed the sulfide. If there is doubt about it, then the procedure should be repeated.

   If it is known that there is no sulfide in the sample, then this step may be omitted.

3. Add 10 mL ammonia and 3 g zinc dust. Then add quickly 10 mL of 5 M sodium hydroxide.

4. Mix vigorously for 15 minutes. A mechanical stirrer is very helpful for this step. An air powered magnetic stirrer can be used with air, water or a compressed-like carbon dioxide in field use if they can be made available.

5. Filter the solution through a rapid filter paper into a titration bottle or flask. As soon as the solution is through the filter, wash the filter with 50 mL of deionized water.

   NOTE: Remove the filter from the funnel and put into a vented jar containing enough water to cover the filter paper. This will eliminate the chance of spontaneous combustion of the zinc dust.

Titration

6. Add 3 mL (4 mL if 100-mL sample was taken) indicator solution to the titration bottle.

7. Titrate the solution with the standard silver nitrate (0.0200 N) to the first cloud point. If the WAD cyanide content is expected to be above 40 mg/L, then use 0.100 N silver nitrate for the titration.

   The cloud point should be just "off white" in shade and should not be dark. If it is dark brown or black, it is quite likely that the sulfide was not removed completely. The analysis should be repeated. Test the solution after the lead carbonate treatment with lead acetate paper or with a bit of lead carbonate to determine if the sulfide removal is complete.

Calculation

8. CN, mg/L = mL $AgNO_3$ x N x 52/mL sample taken x 0.001

   NaCN, mg/L = mL $AgNO_3$ x N x 98/mL sample taken x 0.001

   NOTE: If the Hach digital titrator is used, then the cartridge will probably have the factor on it or it will be in the formation supplied by the vendor.

OBM:mml

9/4/84

0381L

measures differences in conductivity of a silver wire as cyanide reacts with the surface. Ways had to be developed to master interferences by sulfide and copper.

- X-Ray Fluorescence

A miniaturized portable X-ray fluorescence analyzer has recently become available which analyzes over 60 elements semiquantitatively.

By using two radioactive sources and a computer to wash out background effects, the instrument is claimed (by the makers) to be able to achieve much lower detection limits and to avoid interferences. It is claimed to be suitable for water analysis, detecting sources of metal contamination in the field and for continuous monitoring of effluents. Detection of some elements down to 10 ppb is claimed.

The unit is very lightweight, portable, and rugged.

Since it is new and since so many previous portable XRF units did not perform usefully, it is necessary to be skeptical. At the same time, this device has new features which claim to have solved many problems.

RANDOL INTERNATIONAL LTD. would be most interested to hear from anyone who is able to test this device to determine its applicability. Information on the ATX100 portable X-ray fluorescence spectrometor is available from:

ARSENIC

Arsenic is said to be very difficult to analyze accurately at low levels. According to GIANT YELLOWKNIFE MINES LTD., the silver di-ethyl carbamate method of AWWA Standard Methods works well down to 1 ppb and can detect as little as 1 microgram arsenic.

Description of Method

Inorganic arsenic plus zinc dust are reacted in a Gutzeit generator in an acid solution, and the gases passed through a scrubber with lead acetate impregnated glass wool to an absorber tube with silver di-ethyl carbamate dissolved in pyridene or chloroform.

As (Inorganic) + Zn + Acid = $AsH_3\uparrow$

Sulfides + Acid = H_2S + Pb Acetate $\rightarrow$ PbS

INTERFERENCES

Cr, Co, Cu, Hg, Mo, Pt, and Ag interfere with the generation of arsenic--but not in the quantities usually present in water. Antimony salts form stibnine which interferes by forming a red color with maximum absorbance at 510 nm.

Complete details are available from:

AMERICAN PUBLIC HEALTH ASSOCIATION
AMERICAN WATER WORKS ASSOCIATION

"Standard Methods for the Examination of Water and Wastewater," 15th Edition, Washington, DC.

CADMIUM

Evaluation of data for cadmium analyses prior to the mid-1970's seems to show a detection limit around 0.003 ppm - 0.01 ppm Cd. After 1975, AA as been able to detect cadmium down to -.001 ppm reliably with precision using the deuterium arc correction. The technique is essential to avoid misleading high readings by AA. Deunterium arc correction is available for most of the better AA units on the market today.

GOLD ANALYSIS

An AA technique is available which is capable of analyzing gold down to 0.01 ppm in solution without pre-concentration using a direct coupled plasma device. Such a device is now in routine use by, among other companies, WITTECK DEVELOPMENT, INC.

The units supplied by SPECTRAMETRICS, INC. (Beckman ?) sell for C$65,000 each. Photographs of the Spectrum are made as a permanent record.

MERCURY ANALYSIS

Solutions: The Jerome Model 511 gold film mercury analyzer is calimed to be able to measure mercury in solutions down to 1 ppb. The unit costs $3,950 and is in use at ST. JOE MINERALS, Monaca, Pennsylvania, CARLIN Gold Mine, and GETTY Mercur, Utah.

Air Samples: The Jerome Model 411 gold film mercury vapor analyzer measures gold in air down to 0.001 mg/m^3 up to 1.999 mg/m^3. It costs $3,750 for the basic instrument.

The Jerome mercury analyzers are available from:

HOW MUCH CAN YOU EXPECT FROM A PROGRAMMABLE CONTROLLER THIS SMALL?

3753

WITH OMRON SYSMAC-S6

WITH FACTORY AUTOMATION SEIZING THE IMAGINATION OF THE INDUSTRIAL WORLD, demand is growing for programmable controllers (PCs). Controllers which must be compact and multifunction as well as economical and easy to use. For applications like controlling industrial machines or small assembly machines for today's flexible manufacturing systems.

To meet such demand, Omron has developed the Sysmac-S6, a new-age PC which can be built into the machine it controls.

1 NO MORE THAN YOU NEED.

The compact Sysmac-S6 is a fully modular system. This means you can design a configuration that's no bigger than the optimum size for your application. So you get the performance you need at minimum cost, in the smallest space.

2 NO MORE WORN-OUT CAM SEQUENCERS.

Conventional job-step timing control of machine tools or small assembly machines is done mechanically by cam sequencers. And cam sequencers wear out fast. Now, the Sysmac-S6 has replaced mechanical control with software control, using its 32-output-position high speed and reversible counter instructions. Result: vastly improved reliability, drastically reduced operating costs and extremely sophisticated control.

THIS IS HOW MUCH YOU GET.

3 NO MORE RELIABILITY WORRIES.

The all-solid-state Sysmac-S6 is built rugged so it works dependably under any kind of punishment industry can dish out. Vibration, extreme temperatures, dust and electrical noise do not bother this tough little PC—or any of its modules. Such high reliability means virtually no down-time.

4 NO MORE PROGRAMMING HEADACHES.

The console's liquid crystal display (LCD) makes interactive programming and debugging straightforward. Prompted by messages, operators input information via easy-to-understand symbol keys, so no special training is necessary. Which makes even tricky control change-overs fast and fault-free, opening the way to new highs in ladder-diagram program development.

5 NO MORE UNNECESSARY DUPLICATION WORK.

For mass production applications, with just one removable programming console and PROM writer, you can copy your debugged program into as many PROM memory units as you need. Plug a PROM into each CPU, hook up the required I/O units (if any), and what you have is an innovative solution to unit cost problems.

6 NO MORE EXPENSIVE DOWNTIME.

When a fault occurs, swift detection is of vital importance. The Sysmac-S6's comprehensive self-diagnostics cover the programming console's LCD section, key-board and mode selector, and the CPU's various indicators. You can quickly pinpoint what's causing the trouble.

SMART I™

IMPROVED SAFETY, INCREASED PRODUCTIVITY. TOTAL CONTROL OVER THE MINING ENVIRONMENT.

Effective management of the mining environment is essential to profitability. That's why P&MT designed the SMART I system.

SMART I can manage a network of over 3,000 sensors and over 1,000 controlled responses, with split-second accuracy. It continuously monitors every aspect of the mining operation: belt functions, flow rates, bearing temperatures, the presence of toxic gases, etc. Then, it automatically responds to changes in that environment by activating or deactivating pumps, power centers, ventilating fans, and so forth, as needed.

The SMART I Central Monitoring Station is easy to operate and communicates in plain English. It features a powerful microcomputer with over 2 million bytes of information storage, a high-speed printer, and a full-color monitor that shows sensor status along with an exact-scale layout of the mine site. (There is even a 100:1 Zoom feature for a closer look.) And, all SMART I communication is completely self-checked with every data transmission.

The SMART I Remote Sensing Station has 24 sensor inputs, 8 controlled outputs, and a powerful warning horn and light that sounds an alarm whenever a sensor threshold is crossed. With a SMART I Magic Touch Hidden Switch, sensors can even be placed up to 7,000 feet away. During power-outs, it remains fully operational for up to three days, and stores data in memory for as long as thirty days. Housed in a rugged NEMA 12 enclosure, with rubber-sealed packing glands for protection against dirt and moisture, it will withstand the most severe environments. And, like all other SMART I components, it undergoes a Total System Checkout before being backed by P&MT's comprehensive onsite service and parts replacement warranty.

SMART I is easy to operate. It can monitor and control the entire mining environment. And it can operate manually, or automatically according to any control schedule you prefer. A SMART I system is probably the most cost-effective investment your mine could make this year.

For more information about the SMART I system and how it can improve your operation, call your mining, and most important, safety. Call or write today.

P&MT

3756

SPECIFICATIONS

SMART I™ Central Monitoring Station

Microcomputer:	128K microcomputer with 2.4 Mb storage; RS-232C interface to FSK modem.
Printer:	High-speed dot matrix printer with 64K in-line buffer. Wide-carriage option.
Monitor:	14" high-resolution RGB color CRT.
Modem:	FSK at 4800 Baud; Automatic Gain Control; 30 mile range.
Data Transmission:	Uses 2- or 3-conductor twisted pair or, RG-59 coaxial cable.
Power:	120 VAC. Uninterruptable Power Supply available.

The SMART I Central Monitoring Station's high-speed printer prints screen displays and other documents while leaving the computer free to perform its remote sensing and control functions.

SMART I™ Remote Sensing Station

Intelligence:	4K RAM/4K ROM microprocessor (expandable to 64K); 8 analog and 16 digital inputs; 8 digital outputs.
Modem:	FSK at 4800 Baud; Automatic Gain Control; 30 mile range.
Enclosure:	NEMA-12 steel enclosure with entrance glands. Size: 20" x 20" x 8".
Data Transmission:	Uses either 2- or 3-conductor twisted pair or, RG-59 coaxial cable.
Power:	110 VAC via Hubbell connector; 24 amp/hour backup battery built-in.
Analog Input Range:	- 5 to + 5 VDC, without reference. Can be modified to accept other ranges.
Indicator Lamps:	AC power, DC power, Communication Input.

The SMART I Remote Sensing Station can store data in memory for up to thirty days and remain fully operational for up to three days during power outages.

SMART I™ Monitor With Magic Touch™ Module

The SMART I Status Monitoring And Remote Telemetry network is designed to interface with a wide variety of sensors, such as the SMART I CO Monitor with Magic Touch module. The Magic Touch module is an intelligent, stand-alone transmitter that can interface with the SMART I Remote Sensing Station by adding 8 sensor inputs (either analog, digital, or a combination of both) and extend its monitoring capabilities by up to 2,000 feet per channel. The Magic Touch option can be used with a variety of sensors, and is powered by a 3-wire connection directly from the SMART I Remote Sensing Station. Call P&MT for more information on availability (pending agency approval).

Regional offices serving St. Louis, Denver and San Francisco

All products have a 1 year replacement and 90-days on-site service warranty. An extended warranty is available.

CHAPTER 62

IMPORTANT RESEARCH AND DEVELOPMENT FRONTIERS

There are so many directions in water management and treatment technology that need additional research and development that it is clear that the resources are not available to address them all at once. Available R&D resources should first be channeled to the most important problems. Since several problems are common to much of the industry, or at least to groups of companies on a regional basis, it is appropriate that some of the needed research is being conducted as a joint effort.

TAILINGS DISPOSAL AND ACID MINE DRAINAGE

Acid drainage from tailings containing sulfides is by far the most serious root cause of pollution. Several groups have been organized to study fundamental aspects of the problem and to seek better ways of treating or disposing of tailings to avoid long-term problems that the mineral processing and mining industry face.

In Canada, an industry group has been formed to conduct joint research into tailings disposal methods under the auspices of the Canadian Mining Association. It is believed that COMINCO, INCO, KIDD CREEK MINES, NORANDA, and FALCONBRIDGE are members of this group, and more information could be requested through:

JOHN K. WEGLO
Director, Environmental Control
Falconbridge Ltd.
Falconbridge, Ontario
Canada P0M 1S0
(705) 693-2761

Particularly farsighted research into sulfide-bearing tailings disposal from uranium as well as base metal recovery operations has been carried out by CANMET in Ottawa and at a research station at Elliot Lake. Their work aims to understand some of the fundamental processes that take place in tailings materials under different conditions. It is important to examine the root causes of acid mine drainage as well as methods to treat the symptoms of this problem. Having made such a good start, it is hoped that CANMET will continue this work funded by the Canadian government in their national interest:

CANMET
555 Booth Street
Ottawa, Ontario
Canada K1A 0G1
(613) 995-4124

The Chamber of Mines of South Africa is an industry-funded group conducting research into methods of tailings stabilization. Their interest has been mainly directed at inhibition of erosion and dust control. If and when current investigations reveal that tailings and wasterock disposal areas are, in fact, diffuse sources of tds that contribute to the salt load in the Vaal Dam, then further investigations of better ways of preventing or inhibiting them would likely be a natural extension of work by Chamber of Mines Pollution Control Group.

CHAMBER OF MINES OF SOUTH AFRICA
Pollution Control Unit
Post Office Box 2
Regents Park 2125
South Africa
(011) 86-6358
Dan Marsden

There are other industry supported research groups in the U.S.A. which serve the coal industry primarily, such as:

THE WEST VIRGINIA ACID MINE DRAINAGE
Technical Advisory Committee
Dept. of Geology
University of South Carolina
Columbia, South Carolina
(803) 777-3120
Frank Carruchio

Some interesting research which holds promise for the passive treatment of smaller abandoned minesites has been carried out by state organizations such as:

COLORADO DEPT. OF NATURAL RESOURCES
Bureau of Land Reclamation
1313 Sherman, #423
Denver, CO 80203
(303) 866-3567
J. David Holm

Having scored initial successes, this organization has been strapped for funds to take this work further.

Further valuable research into water technology has been funded by the U.S. Environmental Protection Agency which has spent enormous pools of money mainly on seeking ways to treat the symptoms than to find the root causes of acid mine drainage. The U.S. EPA seems to fund organizations and academic institutions with limited experience in the mining and metallurgical industries, and some very hard work has ended up being somewhat out of context at times. Unfortunately, bureaucratic cocoons within this mammoth organization seem to have prevented those charged with directing this research from drawing from the mineral processing industry or from calling on assistance from those in their own organization who have the most experience in this

industry. Partly too, the industry is so afraid of the EPA that this fear has inhibited real cooperation in the past.

In the United States, the Bureau of Mines in Pittsburgh, Pennsylvania, under Dr. Ralph L. P. Kleinmann has conducted very valuable research into how acid mine drainage processes work and how they can be inhibited, and more lately into new low capital cost ways of treating acid mine drainage. Results of their work is available to everyone in the form of publications and industry workshops.

In the end, it will be individual companies and researchers who will find the most practical answers, but the more institutionalized efforts are needed as a springboard if free enterprise principles still work, that is.

The most important R&D frontiers include the following:

1. Determination of tolerance to contaminants in the real life environment.

2. Acid mine drainage inhibition.

3. Water quality effects on metallurgical processes.

4. Water treatment technology for effluents and process water.

5. Biological Treatment processes including ecological engineering.

6. Disposal of precipitate sludges and desalination concentrates.

7. Groundwater quality modelling.

8. Salt balance modelling in metallurgical and mining complexes.

9. Resource recovery from effluents and tailings.

10. Better metallurgical industry insight into dispersants, coagulants, and flocculants.

11. Applicability of impoundment linings and how to install them.

12. Use of water treatment and desalination technology as resource recovery tools.

13. Use of minewater to generate HYDROPOWER.

1. Tolerance to Contaminants in the Real Life Environment

All too often the mining industry decries proposed regulatory limits for various contaminant species on the grounds that they are based on toxicity data established in laboratory tests which do not truly reflect real environmental conditions.

In order to argue convincingly on these grounds that a permit limit is too strict, the mining industry needs quantitative facts. Tolerance to a given contaminant probably depends on the site-specific nature of the environment, climate, and importantly, the other species present in the water as well as the biological species of concern.

Important pioneering work in this direction has been accomplished by Homestake Mining Company at Lead, South Dakota, where Terry Mudder, their environmental control manager, has demonstrated an in-situ bioassay approach in which he shows that sensitive species can and do survive in Homestake's treated effluent.

Demonstrating environmental compatibility of an effluent must surely be safer from an environmental protection standpoint than a set of derived numbers on a permit which were largely guestimates with inordinant safety factors.

This area of R&D, therefore, aims to expand industry's skills and knowledge of applicability of in-situ bioassay techniques as a means of replacing, or at least augmenting, regulatory contaminant limits. Once this has been developed, industry will have a better understanding of "what a particular environment can live with," which will provide a powerful argument to counteract "overzealous" or "anti-industry" idealistic elements in society and the few that still exist in government.

2. Acid Mine Drainage Inhibition

Acid mine drainage is the biggest environmental problem of the mining and metallurgical industry. Methods of treating acid mine drainage involve treatment plants that will have to be operated and maintained "in perpetuity" at enormous accumulating expense to industry and, therefore, indirectly to society.

R&D directed at inhibiting acid mine drainage would address better ways of disposing of wasterock and, particularly, sulfide-containing tailings. Acid mine drainage inhibition in mines is also a vitally important area for further work.

An interesting area of particular interest to explore would be ways to encapsulate the acid generators within the tailings to prevent water getting to these particles in the first place or acid from seeping out. These include application of "subaerial" or "semi-dry" tailings disposal which may require modification aimed specifically at reducing AMD. The

climatic conditions in which sub-aerial tailings deposition will work and types of tailings that will provide adequate encapsulation need to be established.

Another possibility would be to remove the acid generators from tailings for separate disposal or separate treatment, possibly even as a means of recovering valuable by-products in some cases.

Hence, acid mine drainage inhibition involves ways of disposing of tailings, ways of treating tailings, and ways of restoring tailings sites aimed at allowing the operator to walk away from a restored site on completion of the operation.

3. Water Quality Effects on Metallurgical Processes and Equipment

If one cannot discharge an effluent without expensive treatment, then costs can be saved by discharging less effluent. This is likely to mean recycling more process solutions which, in turn, results in a buildup of TDS and contaminant species. These can have serious impact both on metallurgical recoveries and cause corrosion and scale effects in the plant.

The precise effects and mechanisms of how various contaminants affect metallurgical processes need to be understood as well as a means of overcoming those that are detrimental. This may require modifying process conditions--e.g., grinding and flotation in nitrogen rather than air is one example of a way to reduce thiosalt generation in high sulfide ore treatment that could be explored if thiosalts are a problem.

Effects of water quality on flotation processes have been examined, and an interesting start has been made which needs to be carried further to build an insight into precisely what characteristics of water are the cause of detrimental process influences. For example, how can some treated sewage effluents be used in flotation plants without detrimental effects and not others?

Insight of this sort will allow the greater use of alternative sources of water which, at this time, are usually not considered suitable for certain metallurgical processes.

4. Water Treatment Technologies for Effluents and Process Water

Whereas environmental impact of contaminants is measured at levels in the parts per billion range, most water treatment processes in use remove these contaminants to the parts per million range.

Therefore, more powerful and cost-effective processes are needed for removal of many metal ion contaminants to levels that are of interest in environmental protection.

Removal of cyanide and metallo-cyanide complexes are another challenge that requires greater understanding, better technology, and less costly approaches. These may be emerging now in the biological degradation technology recently installed at Lead, South Dakota, and others being tested. Some of the other alternatives that have been applied, including FeS addition, may prove to be more universally applicable, but more practical ways of applying these powerful processes need to be demonstrated to make them more widely applicable. Enhanced natural degradation systems for cyanide destruction deserve attention.

Desalination technologies have been developed into powerful means of making potable water from the sea. However, typical compositions of mine-mill effluents and the need for high recoveries (conversely the need for small volumes of concentrate to be disposed of) is not compatible with conventional desalination equipment. The recent breakthrough in seeded slurry reverse osmosis in mine water treatment described in Chapters 15 and 24 represent the beginning of a whole new perspective for desalination which needs to be tested in more cases. At a treatment cost of R0.50-R0.60 (U.S. 0.25-U.S. 0.30) per m^3, this process is already less expensive than lime addition to high pH in areas located far from a lime source.

Another area where there is room to develop more powerful and more widely applicable technology for water treatment is the high density sludge (HDS) process. Not only does this have advantages in facilitating disposal of precipitates, but it also makes precipitation of contaminants more powerful than conventional precipitation and settling approaches. The HDS process may be expandable to other regimes to further enhance its applicability and usefulness, but this remains to be tested and proven, i.e., another important R&D frontier.

Innovative ways to catalytically oxidize ferrous to ferric iron at a low pH offers a key to iron removal prior to pH adjustment using cheaper limestone which otherwise would be passivated by iron precipitates. These systems need to be further explored.

New developments in cross-flow microfiltration and new equipment is available on the market. This now needs to be applied creatively in water treatment in the mine-mill environment, perhaps combined with creative precipitation techniques. After all, suspended precipitate particles in submicron sizes also contribute to contaminant levels in effluents.

New methods such as insoluble starch xanthates, cellulose xanthates, the Devoe-Holbein pseudo cell media, etc. claim to offer ways of polishing effluents to extremely low metal levels. These need to be investigated, evaluated, and possibly, new applications developed. Not doubt, ways of reducing the cost of these materials and their application will be needed.

As far as removal of suspended solids is concerned when the solids load is very small but must be removed to very low levels to remove suspended metal precipitates, then dissolved air flotation is a powerful technique that needs to be tailored to these needs. DAF may also be used in conjunction with organic solvent extraction or adsorbent removal to reduce effluent metal levels.

New needs for removal of abrasive suspended solids from recycled minewater seem to be emerging, and the new technologies need to be tested and possibly improved upon for specific applications.

5. Biological Treatment Processes Including Ecological Engineering

There is evidence in nature that biological processes can remove contaminants from water. This is nature's own way of cleaning the environment. Mine-mill effluents are more concentrated than most natural effluents and, therefore, to deal with them, natural biological processes need to be engineered to let them match the effluents' treatment requirements.

Interesting experiments have demonstrated useful results in the use of engineered natural marshes for the treatment of sewage. The same principles need to be tested to develop an engineered ecological system to remove contaminants from water in a way that the marsh can sustain itself without becoming destroyed by the toxicity of the metals it has removed from the water. Whereas most research in the past has explored metals uptake by plants, by algae, and by bacteria separately, the key here lies in an engineered ecological system which combines all three in coexistence with each other.

The rest of this century has been identified as the dawning of the age of bioengineering, and this is opening up new frontiers and understanding of biological processes as well as offering new equipment which will be useful in the treatment of mine-mill wastes and effluents.

Reference is made already to the use of bacteria in cyanide destruction of effluents. Research has also been identified into the use of bacterial to detoxify heap leaching tailings after cyanidation. This work is being pioneered by Envirologic Services International.

Advanced Mineral Technologies of Socorro, New Mexico, has developed a new biological process for the removal of metal ions from effluents, which they also are engineering as a means of recovering resources.

John Spisak of Anschutz Mining Corporation wrote about algae that take up very high concentrations of arsenic which could be useful as a means of removing arsenic from effluents.

David Holm of the Colorado Dept. of Natural Resources showed how natural marshes can remove contaminants from acid mine drainage, and there is evidence that a series of beaver ponds on streams have natural cleansing effects on water rendering AMD contaminated water viable for trout.

Japanese workers and CANMET have demonstrated that acid mine drainage can be treated by passing it through wood shavings or sawdust which support biological activity when augmented with organic nutrients.

Biological processes are known which convert sulfates to elemental sulfur or sulfide. These would be useful first to remove sulfates from water with high TDS level problems--e.g., minewater on the Witwatersrand--or to precipitate contaminant metals as sulfides. Sulfate removal and metal sulfide removal has been observed in natural settings and may be engineered into useful processes. The argument that too much land area would be required for marshes can be countered by showing the large areas surrounding tailings areas in various parts of the world that today already accommodate marshland.

Biological processes represent a promising frontier and, with research and development, more of these may be developed into useful techniques to help solve some of the many problems in water treatment facing the mining and milling industry.

6. Disposal of Precipitate Sludges and Desalination Concentrates

In treating large volumes of effluents to remove contaminants, most processes yield smaller volumes of much higher concentrations of these contaminants. These, of course, are usually more toxic or at least are less desirable than the original effluent and must be disposed of safely.

Various methods have been developed to encapsulate this type of waste, but these can often be expensive. It remains to determine whether the common practice of adding them back to the tailings pond is a safe permanent way of disposing of these materials, or whether it can be made to be so. Chloride levels would be an area of particular concern here.

Bethlehem Steel Company has shown that HDS sludges can be mixed with small quantities of cement or flyash and lime to form pozzolons suitable for disposal in sanitary landfills. This could be a start in a more widely applicable way of safe disposal of precipitates.

Deepwell disposal of desalination concentrates has been considered along the lines of toxic waste disposal by the chemical industry, but this is not very economical either.

Another technique of disposing of desalination concentrates may be through evaporation in ponds and, again, more needs to be known about how to make safe, leakproof evaporation

ponds, on liner selection and installation, and about final closure of these ponds on completion of a project or when they have filled with salts.

7. Groundwater Quality Modelling

Impoundment linings are very expensive and also, if seepage is eliminated, these can cause other salt and water balance problems in some metallurgical operations.

In some cases, natural geochemical attenuation of contaminants in seepage is sufficient to allow seepage to take place. To be able to know where this is safe and where it is not, more knowledge of groundwater quality modelling is needed.

8. Salt and Water Balance Modelling

Water balance modelling to take into account water gain and loss at each component of a mine-mill-tailings complex is relatively easy until complicated by naving to make decisions on routing of streams and degree of recycling of solution based on their salt load. This is where salt balance modelling would be most useful if it could be achieved reliably, based on experimental data.

Before a mine-mill-tailings operation can be licensed in most countries today, the operator must demonstrate how water will be used, how much may have to be discharged, and what its quality will be. Judgements must be made on the amount that can be recycled within equipment and process constraints. To do this in advance requires a good water and salt balance model. However, salt balances, especially for operations that recycle solutions allowing dissolved solids levels to build up, are very site specific and ore-specific. That is, the degree to which salts will dissolve into solution or be removed from solution also varies with chemistry of the gangue in the ore, and other site-specific aspects that may not be known in advance.

The problem of dealing with numerous equations expressing equilibria of various components in solution and numerous process streams and loops can be dealt with using powerful computers available today. However, how one contaminant affects another and the effects of gangue characteristics and reagents used or surfactants employed in the process on salt solubilities are not yet clearly quantifiable. Much more R&D is needed in this area to develop a useful salt balance modelling technique for complex solutions. This has been achieved for power station cooling water by CALGON CORP., and several consultants have made a good start in salt balance modelling technology. However, those interested in developing this technique should be prepared to invest many years and many millions of dollars before they might have a really reliable tool. This remains a most needed R&D frontier, however.

9. Resource Recovery from Effluents and Tailings

While the mining industry seeks ways of inhibiting acid mine drainage, a chemical engineer in the U.S.A. has developed a concept for hydrogen gas development as a source of energy. To him, an acid stream at pH 2, a source of granular pyrite and scrap iron, would be a potential bonanza.

Imagine if sulfide tailings could be disposed of in such a way that rather than inhibiting acid generation, ways are sought to accelerate sulfide oxidation (e.g., bacterial), thereby generating acid faster but also oxidizing the tailings faster to a point that they are exhausted in say 20 years as opposed to the present 300-500 year timeframe. Pyrite removed from the ore or tailings would be consumed as one galvanic cell electrode and scrap iron gathered locally from various sources as the other, to generate hydrogen. Such a concept is a "long shot," but it does have such a valuable potential if only to avoid the prospect of "perpetual" treatment plants and tailings site maintenance at the many mining centers around the world.

This concept has not progressed beyond the idea stage. It was conceived by:

PROFESSOR AL STILLER
Chemical Engineering Dept.
University of West Virginia
Morgantown, WV

The important point is that effluents may contain valuable by-products which can change one's approach. But more R&D is needed in this area.

Many effluents contain valuable metals. At most gold mills that discharge an effluent, residual gold values can be recovered from these effluents. Attempts are even being made to recover gold values from an acid mine drainage flow from an abandoned base metal mine in California, for example, as well as from oil field brines.

In Peru and Chile, copper is recovered from minewater. In the U.S.A., uranium is recovered from minewater draining from copper and uranium mines. On the Witwatersrand, a series of metals could be recovered by selective precipitation or selective extraction from gold and uranium mine effluents, if the price of cobalt, nickel, and manganese ever got high enough. Creative approaches at biologically accelerating AMD generation in sand dumps to yield recoverable gold and uranium values may be more realistic in the short term while helping to neutralize residual AMD generating capacity of low grade tailings.

Water treatment plant sludges containing high metal values have been disposed of with smelter or roaster feed where some incremental values have been generated.

In other industries, biomass generated in biological waste treatment is used to generate methane gas an an energy source--could .this be a possible by-product of biological effluent treatment in the mine-mill environment in some parts of the world?

In Scranton, Pennsylvania, mine drainage is reputedly used as a source of heat in winter and a means of cooling buildings in summer.

New developments have come to light in the recovery of cyanide values from gold mill effluents where the ore contains high concentrations of cyanide soluble copper. This was practised years ago in Canada and Mexico, but the new process has been demonstrated by MNR Reprocessing, a subsidiary of Metallgesellschaft, and Mountain States Mineral Processing, Inc. Cyanide recovery from effluents is certainly a worthwhile R&D frontier considering the cost of cyanide destruction alternatives.

Other areas in R&D include the use of desalination, e.g., electrodialysis, as a means of recovering reagents, e.g., H_2SO_4 and NaOH from Na_2SO_4 effluents. Elsewhere, the use of R.O. in water treatment to make potable water also generated a concentrated Na_2CO_3 stream with potential by-product recovery potential.

Through R&D, more examples and better economics of resource recovery from effluents can be expected. In general, however, recovery of base metals from most effluents does not look economically attractive at today's metal prices.

10. Better Insight into Dispersants, Coagulants, and Flocculant

As attempts are made to reduce the capital cost of installations by making smaller units work harder, increasing use is being made of reagents which are dosed at small amounts to modify or inhibit scale characteristics of water, reduce corrosion, enhance settling rates, and improve clarities or slurry rheology. Several water treatment chemical companies serve this market. Sometimes relatively cheap materials and even waste material from other industries are used as surfactants for these purposes.

Mineral processing operations would not dream of employing a metallurgical process, reagent, or item of equipment unless they know exactly what it is, how it works, or what impact it might have elsewhere in the plant. Yet, when it comes to water treatment services and products, they are usually satisfied to trust the supplier of those services and products implicitly. This may be recognition of the complexity of some of the chemistry sometimes involved or of the AXIOM that a little bit of knowledge is dangerous.

Many of these surfactants and water treatment additives are so powerful that the mining industry might benefit well from more R&D to learn more about the fundamentals and practical cost saving ideas in this [illegible] which, to most metallurgical and water treatment engineers involved in mining, rem[illegible] a "black art."

11. Applicability of Impoundment Linings and How to Install Them

Even based on a small sampling of installations, there have been enough cases of failure or problems associated with linings of impoundments for this to be added to the list of R&D frontier needs.

R&D in this area needs to think in terms of a lining system rather than just a lining.

Lining salesmen are a major source of valuable information on linings, but what is needed is a detailed survey of the practical aspects of selecting, testing, and applying linings for solution, tailings, and water impoundments, as well as a catalogue of pitfalls.

12. Use of Water Treatment and Desalination Technology as Resource Recovery Tools

Although several processes have been looked at as a means of treating water to make it potable, useable in metallurgical processing, or dischargeable as an effluent, some of the desalination techniques could possibly be developed into concentrating processes.

Examples include reverse osmosis and electrodialysis, liquid-filled membranes, biological processes, and certain adsorption processes, etc. Some attempts to develop electrolytic recovery techniques to both recover metals and remove contaminants have been made so far without economic success.

13. Use of Minewater to Generate Hydropower

When water is needed underground for whatever use, it usually is supplied from the surface. There is a significant hydrostatic head at the underground tap of a mine some thousands of feet below the surface, and special high pressure pipes must be used.

This hydrostatic head is being harnessed to drive hydropower generators and even to drive hydraulic tools and equipment. The latter was announced by the Chamber of Mines as a new development and, undoubtably, more R&D will turn this into a routinely used source of energy in underground mines.

The above list some of the R&D frontiers that need to be addressed. Undoubtably many more have been left out. Clearly, this a worthwhile area to invest research and development funds at this time. In many cases, processes or equipment already exist that can fulfill needs of industry. It is a question of finding and adapting them to fill specific needs.

INTRODUCTION

The Beisa Mine was designed to produce uranium and gold from a typical Witwatersrand quartz pebble conglomerate ore. The mine is located south of Welkom on the southern edge of the Witwatersrand in what is known as the Orange Free State Goldfields.

The gold mill uses carbon-in-pulp. The uranium plant uses sulfuric acid leaching, belt filtration followed by solvent extraction.

The Beisa Mine is a wet mine and considerable quantities of water must be pumped from underground.

Beisa minewater is high in chlorides and until the 1982-4 drought resulted in the need for emergency measures, the water was evaporated to dispose of it. Since the drought resulted in a severe shortage of water, it has been settled and used in the process.

EVAPORATION POND QUALITY

pH	9
TDS	4042 ppm
Cl^-	2080 ppm
Total $CaCO_3$ hardness	370 ppm
$SO_4^=$	122 ppm
Suspended solids	Less than 10 ppm

WATER TREATMENT None, settling to remove suspended solids.

WATER USE

The operation was started up using Orange Free State Water Board fresh water. During the drought, the plant converted to using the high chloride minewater except where fresh water is essential - that is for solvent extraction and ADU washing in the uranium plant, for carbon elution in the gold plant.

EFFECTS OF WATER QUALITY

No ill effects had been noted on metallurgical recovery by the operators. Presumably, because there is an excess of water it does not have to be recycled many times so a further buildup of TDS is avoided and raffinates can be discarded to evaporation. No serious corrosion effects had been observed that could be blamed on water quality. The walkways on the gold plant were getting rusty. The gold filter plant uses stainless steel 316L which is corrosion resistant and no ill effects of the high chlorides have been observed yet.

The operators had some initial concern about using minewater as washwater on the belt filter plant. To their surprise they found that the high TDS, high chloride water gave a 20% faster filtration rate than OFS Water Board fresh water.

DISPOSAL OF EXCESS WATER

Beisa minewater is too high in chlorides to be discharged as effluent. Beisa disposes of excess water and solution bleeds by evaporation which has been found to be more cost effective than desalination and recycling. It was planned to pump excess water to the St. Helena mine and mill which is short of water and located just a few miles away.

EVAPORATION

It is believed that the following paper by BENTEL & JAMES (1983) refers to disposal of water from an OFS mine, presumably Beisa; it provides an interesting insight into design and costs of evaporation ponds in South Africa.

MINE WATER

Design aspects of EVAPORATION DAMS

General view showing typical land coverage of evaporation dams.

By D L BENTEL and B M JAMES, both of Steffen, Robertson & Kirsten, Mining and Geotechnical Engineers.

THE RECENT DEVELOPMENT of a new mine in the OFS goldfields has led to considerable quantities of underground water being pumped to surface.

In addition, disposal of effluent water from the mine tailings and raffinate dams is required. This underground and effluent water is not suitable for drinking, irrigation, stock-watering or discharge into a water-course.

Detailed analyses indicate that the cost of purifying the underground water, so that it conforms with regulations, is about three times the cost associated with evaporating the water. Consequently, the most economical and practical method to dispose of underground and effluent water is an evaporation-dam system.

This article describes the design philosophy adopted for both the

evaporation dam systems constructed to date and proposed future systems. Engineering, economic and environmental considerations are discussed.

Hydrological Considerations

Fig 1 illustrates the typical water balance affecting the evaporation-dam system.

Hydrological data from Hydrological Research Unit reports Nos 1/72 and 2/73 and Weather Bureau publications are used to determine the minimum area required to evaporate sufficient water to achieve an acceptable balance.

Tables 1 and 2 summarise average monthly precipitation and mean monthly evaporation figures for Odendaalsrus.

From these tables the theoretical minimum net monthly loss due to evaporation only (*i.e.* not including seepage losses), is in July and is of the order of 0,45 Mℓ/ha. The average annual net monthly loss due to evaporation is of the order of 0,85 Mℓ/ha.

Recent on-site measurements indicate that a total minimum loss (including evaporation and seepage) of the order of 1,0 Mℓ/month is reasonable for July. This figure has been used to determine the minimum evaporation area required.

It should be noted that an evaporation tank (Symons Type T) and a competent rain gauge have been installed to monitor on-site precipitation and evaporation and hence aid in the determination of variable inflows and outflows.

THE FOLLOWING section describes the design details used to develop an available area into an evaporation-dam complex.

Wall height

The minimum wall height is determined according to the criteria set out in regulations made in terms of Section 26 (c) and (d) of the Water Act, 1956 (Act 54 of 1956).

The relevant clause 11.1 states:

"The storage capacities of all sumps and dams shall be sufficient to ensure a freeboard of at least 0,5 m above the expected maximum water level, which shall be based on the average monthly rainfall figures for the catchment area concerned, less the gross mean evaporation in that area, plus the maximum precipitation to be expected over a period of 24 hours with a frequency of once in 100

FIGURE 1: Water balance affecting evaporation system.

TABLE 1: Average monthly rainfall figures for Odendaalsrus

Month	OCT	NOV	DEC	JAN	FEB	MAR	APR	MAY	JUN	JUL	AUG	SEPT
Evaporation (mm)	46	66	72	89	73	76	46	22	8	9	7	13

TABLE 2: Mean monthly evaporaton figures (HRU 2/73)

View of wall showing upstream and downstream rip-rap and crossfall on crest towards upstream side.

years, according to information obtained from the Secretary."

To comply practically with this regulation in terms of freeboard and storage capacity, the minimum wall height considered is of the order of 1,0 m. The spillway level is 0,5 m below the crest level.

The maximum wall height is of the order of 2,0 m. A higher wall of the same cross-section requires incorporation of underdrainage to control the phreatic surface. This involves additional expense (R30/m of wall). Dissipation of accumulated seepage water in the underdrains is impractical because ground slopes are flat and substantial "dead" area is required to gravitate water. This reduces the total evaporation potential of the area.

Wall construction

A typical wall cross section is shown in Fig 2.

Compacted earth wall and key

Sound engineering practice, as well as legal criteria, are the prime reasons for specifying compaction of earth walls and keys.

Clause 11.4 in the "Water Act" states: "All sumps and pumping

FIGURE 2: Adopted wall cross-section.

installations, including catchment dams for recycling of water, shall be of a design and of adequate capacity to prevent the uncontrolled release of water at any time."

Clause 12 states: "The manager of a mine or works shall ensure that any material, tailings and waste rock dump and any slimes, barrier or evaporation dam, stormwater drain or other waterway is as far as practicable located and designed so as to minimise the possibility of damage thereto by subsidence, settlement, shock, and cracking due to past, present and future operations at the mine or works."

Compacting the wall and key material increases the strength and hence decreases the permeability and seepage through such material. If compaction is not carried out on the in situ sands and clays the

FIGURE 6: Relative construction costs for evaporation dam systems.

resulting seepage and inherent lack of strength would result in wall failure and hence uncontrolled release of water.

Inclusion of the compacted key ensures that the wall is not founded on in situ aeolian sands which display collapse potential. Differential settlement along the wall length is thereby minimised.

In addition, by extending the key to a reasonable depth below natural ground level, *i.e.* to a depth where the relative permeability of the in situ earth is much less than that of the highly permeable aeolian sands, seepage under the wall is reduced.

The least depth of the key is about 400 mm. This prevents differential settlement.

The greatest depth of the key depends on the seepage that may be tolerated. The depth of the key in walls adjacent to the farmer's should be greater than in internal walls, or in walls adjacent to mine property on which seepage water may be tolerated.

Crest

The crest width is determined according to the minimum width of plant required for compaction. The most economical method of constructing evaporation dams is with mechanical scrapers and conventional plant. A crest width of less that 3,0 m is thus both impractical and unsafe. A 2,5 % crest crossfall is incorporated to encourage stormwater falling on the crest to flow towards the upstream slope. This reduces erosion of the unprotected downstream slope.

Sideslopes

The evaporation dam walls are constructed with in situ material which varies from silty sands to sandy clays. The strength and permeability characteristics for these materials have been used to determine the stability of the walls for operating conditions. Stability analyses have shown that for a crest width of 3,0 m, and a wall height that varies from 1 to 2 m, a minimum side slope of 1 (vertical) to 1,5 (horizontal) *i.e.* 33,7 %, ensures an acceptable factor of safety against sliding and slip-circle failure. In addition, this angle is less than the average angle of friction of the dump rock rip-rap protection. Hence sliding of the dump rock is minimised.

Rip-rap protection

Coarse waste-dump rock is specified for the entire upstream slope to prevent erosion of the earth wall due to wave action. The same is applied to the downstream toe to prevent erosion due to wave action as well as to form a toe buttress and toe drain. The maximum vertical height of the downstream rip-rap is of the order of 0,5 m.

Damage to wall resulting from wave action against inadequate rip-rap.

FIGURE 3 Adopted spillway cross section

Spillway construction

A typical spillway is shown in Fig 3.

Cut-off trenches and drains

Cut-off trenches and drains are required around the perimeter of the evaporation dam systems to prevent migration of seepage water into adjacent farmland.

Clause 11.3 of the Water Act states: "French drains and ditches to catch seepage water and carry it to evaporation dams or to sumps for recyling, shall be constructed at all tailings dumps wherever seepage occurs."

This clause has been applied to evaporation dams.

Two methods used to cut off seepage are shown in Fig 4 and Fig 5 (next page).

Cut-off trenches and drains are designed to gravitate towards sumps at low points adjacent to the system perimeter. From these sumps seepage water is pumped back into the system.

To reduce pumping, seepage water flowing within the cut-off trenches is gravitated, where possible, into downstream dams by means of weirs and pipes. The cut-off trench is designed, where possible, to in-

tercept seepage within the relatively permeable aeolian sands.

It should be noted that for economic reasons, the OFS mine has decided not to incorporate seepage cut-off trenches around all of the systems.

A DETAILED study has been carried out to determine the most cost-effective method of developing evaporation area for varying average ground slopes.

Fig 6 (next page) shows the relationship between construction costs per developed hectare, and average ground slopes, for varying wall heights, and the following information can also be otabained from the same graph.

(i) For ground slopes varying from 0,25 % to 1,2 % the most economical evaporation dam system is 1,5 m high walls at 1,0 m contour intervals.

(ii) For ground slopes greater than 1,2 %, the system based on 2,0 m high walls at 1,5 m contour intervals becomes most economical.

(iii) The system based on 1,0 m high walls at 0,5 m contour intervals tends to become highly uneconomical, as the ground slope increases.

FIGURE 4: Open cut-off trench.

FIGURE 5: Closed drain.

DURING CONSTRUCTION of the evaporation dams, the following items have been found to be of major importance.

Survey and measurement

To ensure that maximum ground use is achieved, wall location and height, and spillway levels required great accuracy during construction. To this end, the contractor is required to submit survey data on a regular basis. These data are also required for accurate measurement of quantities.

Wall material and compaction

Constant control is required to ensure that acceptable borrow material is used for wall construction.

The present method of establishing borrow pits adjacent to the wall under construction, has led to the more sandy material (*i.e.* upper layers of borrow) being used in the lower regions of the wall, *i.e.* "key" and base.

Consideration should therefore be given to greater control of the location of borrow areas in order to achieve wall construction which incorporates the clayey material in the lower wall regions and hence minimises seepage. The more sandy material should be placed in the upper regions.

The borrow material is placed in loose layers not exceeding 200 mm in height and compacted by approved vibratory or impact compaction plant. The specified compaction is 100 % Standard Proctor density at a moisture content between 1 % below and 3 % above optimum moisture content. Compaction testing is carried out in each layer to ensure that the above specifications are met. A competent soils laboratory is required on site to ensure that the frequency of testing is sufficient to provide conclusive evidence of satisfactory compaction and to avoid delays in obtaining data.

Rip-rap

Loose material on the upstream face has a detrimental effect on the rip-rap layer in terms of post construction settlement. It is therefore essential to ensure that the upstream face is cut back to competent, well-compacted material prior to placing rip-rap. It is necessary for the contractor to over-build to achieve both the above criteria and the design cross-section.

The use of finely graded dump rock for rip-rap should be avoided where possible. If fine material only is available, as was the case in the construction of one of the evaporation dam systems, bad erosion can be expected.

The measures adopted as a result of the above are to increase the

height of the rip-rap, *i.e.* construct a "mound" of rip-rap on the upstream crest edge. Thus extra material was pushed down to reinstate eroded areas, with very limited success.

Increasing the thickness of the rip-rap may be considered. However, the cost of this is inhibitive. The most acceptable solution is to allow erosion and stabilisation of the rip-rap to occur, and then reinstate, using coarse material when it becomes available.

BAD EROSION of the downstream slope of the earth wall has taken place due to rainfall run-off, despite design and construction measures taken to prevent this, *i.e.* cross-fall on crest. The above is particularly bad at wall intersections. To prevent this, vegetaion should be established on the earth walls.

Regulated Inflows

The regulated inflow to each phase of the total system requires constant monitoring to ensure:

- That the depth of flow over spillways is not excessive in terms of acceptable freeboard;
- That optimum use of evaporation area is achieved.

Sufficient surge capacity is maintained by keeping topographically lower dams dry. As soon as spillage commences into the dams reserved for surge capacity, the regulated inflow into that system should be controlled to ensure that it is compatible with current achievable losses. A no-spill situation is set up while maintaining maximum allowable area coverage.

To achieve this, accurate measuring devices are required to record regulated inflows and outflows, precipitation, evaporation losses, and seepage losses. These measuring devices should be installed during construction of the dams.

Pollution

Periodic monitoring of boreholes in the immediate vicinity of the evaporation dams has revealed that little change in water quality has occurred since commissioning of the initial dams in 1980.

A change of surface-water quality has occurred at two seepage-trench sump areas where pumping of seepage water has been insufficient to prevent accumulation, and consequent migration into adjacent farm lands. It is therefore extremely important to ensure that the necessary equipment for dissipating seepage water is installed and fully functional before commissioning of any evaporation dam system.

In conclusion, the evaporation dam systems constructed to date have been successful in achieving their design function, *i.e.* to dispose of mine underground and effluent water in an environmentally acceptable fashion.

However, greater control is required with respect to the operation of these systems to prevent localised contamination of adjacent farmlands.

INTRODUCTION

Cotter Corporation is currently preparing an application for renewal of their operating permit from the Colorado Dept. of Health for the Canyon City Mill.

The company declined to provide information on their water management and/or water treatment facilities on the grounds that they are "not atypical of the industry." Cotter

Corporation has for a long time been under the scrutiny of environmentalists and regulatory authorities, perhaps more so than others because of the proximity of their operations to metropolitan areas and because water discharged from these plants migrates toward usable water sources for these areas.

It is appropriate to summarize some of the details of water management and treatment that is practiced by Cotter Corporation, much of which has been pieced together from fragments. The data is not completely as reliable but useful only to provide a broad picture of some of this company's challenges and achievements.

Of particular importance is the remarkable performance of a continuous ion exchange plant for removal of uranium from 2-3 ppm down to 10-12 ppb and less, which is a demonstration of just how effective fixed bed IX systems can be. This is the first continuous fixed bed system that has come to our attention.

DESCRIPTION - MINE

Cotter Corporation operates the Schwarzwalder uranium mine just north of Golden, CO. Ore is crushed and upgraded using radiometric ore sorting to produce a beneficiated ore for shipment to the Cotter Mill at Canon City, CO. Excess minewater is treated first to remove radium and then uranium. New effluent discharge limits in Cotter Corporation's permit were set at 40 pCi/l which is equivalent to 59 ppb U_3O_8 in 1979. A new ion exchange entraction process was developed by Cotter Corporation, Himsley Engineering and The Diamond Shamrock Company as described by JACOBS et al. (1979).

Flowrate of water treated is 500 USgpm and the treatment plant is operated at that rate. Water is pumped from underground resevoirs to a surge tank at the surface and arrives at the plant at a constant pH of 7.5 - 7.8 and requires no pH adjustment. Radium and uranium must be removed.

The primary treatment step is removal of particulates and radium. This is achieved by dosing $BaCl_2$ to the surge tank. Coagulants are added in a mixing tank downstream from the surge tank. There is adequate sulfate in the water at about 500 ppm to coprecipitate radium as $\underline{BaRaSO_4}$. At this point the water has 200-300 ntu turbidity (sometimes as high as 500 ntu.) This is followed by a 35' outdoor conventional clarifier and indoor filtration through two deep bed sand filters. Particulates at this point have been dropped to about 0.2 ntu's. To achieve this NALCO flocculant polymers of both the cationic and anionic types are added. Clarifier underflow sludge is dewatered on a drum filter and added to the ore. Sandfilter backflush sludges are returned to the clarifier.

The clarified water is next pumped at a constant rate of 500 USgpm to the downflow continuous moving bed ion exchange columns designed and installed by:

Himsley Engineering
250 Merton Street
Toronto, Ontario M4S 1B1

Telephone: (416) 485-4441
Contacts: Alec Himsley, President
Al Peterson

Finally the water discharges to the first of the original five barrens ponds leaving the remaining four ponds for use as an emergency catchment pond for use should any part of the facility be down for repair. The whole water treatment plant requires just one dayshift operator.

The Himsley continuous fixed bed ion exchange plant installed at the Schwarzwalder Mine is a unique and innovative design with an extraordinarily high efficiency. It consists of two downflow fixed bed ion exchange adsorption columns connected in series. The columns are closed tanks engineered as pressure vessels. The elution system consists of a single downflow column.

Uranium adsorbs as the uranyl carbonate complex and is reduced from 3 - 3.5 ppm U_3O_8 in the feed often to below 10 ppb in the effluent. Loaded resin is fluidized at the top of the lead adsorption column and transferred to the bottom of the desorption column via a 3 ft^3 measuring vessel. An intermediate step washes the resin with spent eluate to convert $CO_3^=$ to CO_2 which is vented. If this were not done, CO_2 gas in the fixed bed elution column would cause channelling and interfere with elution efficiency. Eluted resin is transferred from the top of the elution column to the bottom of the tail adsorption column. Transfer is via a pressure vessel and pressurized transfer of a resin slurry in water. The following details summarize the IX operation which was commissioned in 1982. The IX plant was described by PALMER, et al. (1984).

Loaded resin, after pretreatment with spent eluate is eluted with sulphuric acid. The eluate contains 10-15 g U_3O_8/l - in other words the ion exchange process achieves a 3,000 fold concentration ratio which is remarkable.

ADSORPTION

Flowrate	:	500 USgpm
Uranium in	:	3 - 3.5 ppm U_3O_8
Uranium out	:	10 - 20 ppb U_3O_8
Column diameter	:	4 - 7 feet
No. of stages	:	Two downflow columns in series
Resin depth	:	6 - 7 feet in each column
Column vessel height	:	10-12 feet (estimated)

Dowex resins are believed to have been used. Lately a test batch of Rohm & Haas anion exchange resin has been loaded into the system. A batch of Diamond Shamrock Duolite A101D anionic resin has been ordered to test. Cotter Corporation is looking for ways to reduce the cost of resin.

RESIN LOADING Resin is loaded to 35 g U_3O_8/l of resin.

RESIN TRANSFER

Periodically a measured volume of loaded resin is transferred from the adsorption column to a measuring vessel. The uranium loaded as uranyl tricarbonate is converted to uranyl tri-sulfute using free acid in the eluate with release of CO_2 in the measuring chamber.

ELUTION

Resin is eluted with 13% sulfuric acid also in a multi-stage downflow column. Loaded resin is injected into the bottom of the column and eluted resin extracted from the top of the column during the resin transfer cycle. Counter current elution of several batches of resin in series (U.S. Patent No. 401 8677) produces a more concentrated eluate than other systems, thereby reducing transportation costs to the mill. After a batch of resin leaves the elution column, it is washed with barren solution in the rinse chamber to remove excess sulfate before being transferred to the bottom of the adsorption column.

RECENERATION

A regenerating chamber is provided to clean the resin should it become fouled with silica or molybdenum. A selector switch on the control panel permits the operator to regenerate as much of the resin as necesssary to maintain the ash content at a level that will permit good loading and stripping to meet effluent regulations.

ELUATE

With feed concentrations at 3.0mg U_3O_8/l and barrens at less than 0.01ppm U_3O_8, the eluate averages 12g U_3O_8/l. Periodically it is shipped to the mill, which is about 125 miles from the mine and fed directly into the precipitation circuit for production of yellowcake.

RESIN LOSS Resin replacement has been about 7% per year.

OPERATORS

The CIX plant is the responsibility of Mr. Carles Palmer who also supervises the radiometric ore sorter plant. The CIX plant is operated by two full operators each working four 10-hour shifts per week and overlap on one day of the week. An alarm system alerts mine personnel to malfunctions while the plant is unattended.

OTHER ASPECTS

Copper, cadmium and lead levels in the water are said to be close to the permit limits. A study is in progress to determine the need for and processes available to remove these metals too.

MILL

Located at Canon City, Colorado, beneficiated ore from the Schwarzwalder Mine is leached to recover uranium. In earlier days unbeneficiated ore was treated which yielded larger volumes of tailings. At the Cotter Corporation Canon City facility there is an old millsite which is no longer in use and the new mill that replaced it is located on the same property. The old abandoned mill has been fenced off and it is expected that in 10-15 years or so it will be demolished and the site restored.

Several unlined old tailings disposal areas exist at the mill some of which are now used as ore stockpile areas for the new mill.

Numerous monitor wells are scattered around the Cotter Corporation plant and tailings site to define groundwater effects and migration of contaminants.

A few miles from the Cotter operations at Canon City is located Lincoln Park and a municipal drinking water SCS reservoir which serves the town. Seepage from the Cotter past and present operations is slowly migrating toward the reservoir and is contaminating groundwater with uranium, molybdenum and selenium.

A principle source of this contamination appears to be seepage through several old tailings impoundments which were in use since 1958. All tailings for the first 25 years of operation were deposited on unlined natural ground surfaces. The soil and groundwater underlying this area is contaminated by metals to the extent that it could take 50-100 years to decontaminate the groundwater by reversing the flow and flushing out the contaminants.

The migration rate of contaminated groundwater toward Lincoln Park is slow and is being monitored. The aquifer is artesian and the water table at places is 2-3 feet below the surface, elsewhere it is 30 feet deep. The main aquifer underlying the area is said not to be contaminated.

The contaminated soil layer covers 80 acres and is 6 feet deep. The soil is sandy and has become consolidated in places requiring ripping to penetrate. It is not vegetated.

Cotter Corporation is faced with two choices:

1) To remove contaminated topsoil
2) To isolate the contaminated material and prevent further seepage through it.

It is proposed to isolate the contaminated material by covering it with a 2 ft thick compacted clay layer. At the same time the already contaminated groundwater that is migrating toward the reservoir can be intercepted at a gap in the bedrock where it is planned to contain it. A series of measures including drains, downstream cutoff trenches and surface sealing are under review to determine the cost of solving the problem.

Morrison-Knudsen was retained to undertake an extensive investigation into the alternative remedial possibilities at the Canon City millsite and their costs. A report was due to be presented to Cotter Corporation mid 1984. The project manager for Morrison Knudsen at Boise, Idaho was Bill Gossett (208) 386-5422.

There is already a stockpile of clay rich soil that could possibly be used to install a compacted clay surface capping over the site. It is not known how surface cracking would be prevented except possibly by covering with topsoil and seeding.

TAILINGS DAM

The Canon City tailings are now deposited in a lined tailings pond designed by:

Wahler Associates
1023 Corporation Way
Palo Alto, CA 94303
Telephone: (415) 968-6250
Contact: Forrest Gifford
Jack Wulff, President

The pond lining system is installed over an underground drainage system installed on the bedrock to catch and recover any seepage. The bedrock itself was cleaned and sealed then covered with an 18" compacted clay layer which acts as a base for a hypalon liner. An interesting feature of the lining membrane is that three thicknesses are used increasing with depth as hydrostatic head increases: believed to be 30, 35+ and 45 mil but subject to confirmation. The liner is covered with earth and finally a sequence of liquid drains installed over the lining system at the base of the tailings. When filled the

tailings pond will be covered with a layer of clay, then earth and rock followed by topsoil for seeding.

COTTER PROJECT

Project Background and Setting

The Cotter Corporation began operating its first uranium mill in August 1958, near Canon City, Colorado. The original tailings dam was developed from a starter dike; further construction of the tailings impoundment was done with mechanical equipment using tailings sands, a normal method of construction at that time. Over the years, the plant expanded to meet the growing demands of the uranium industry. The tailings system was expanded along with the mill as required. In 1975 Cotter Corporation decided to construct a new mill adjacent to the then existing mill. The new mill, which has a capacity of 1360 metric tons per day (1,500 short tons) of ore, will handle new ores from various mines. It is planned that the refurbished old mill will reprocess tailings from the existing ponds for additional mineral resources recovery. The new mill produces acid wastes and the old mill produces alkaline wastes. Because of chemical considerations, the waste products are kept separate. Thus, two impoundments are required. No recycling of liquid wastes is performed. These will be disposed of by evaporation from the tailings pond. A plan of the facilities is shown on Figure II-1.

Since the solid and liquid wastes from uranium processing are toxic, one of the most important concerns in the design of the new tailings disposal facility was containment of the wastes, i.e. seepage control to prevent the degradation of downgradient waters. This is especially critical at the Cotter facility, because it is located at about Elevation 1700 m (5600 ft.) only 3 to 5 km (2 to 3 miles) upgradient of Canon City and the Arkansas River. In addition, the existing tailings ponds, which were constructed when proper uranium tailings disposal and pollution control were not fully understood or appreciated, have raised concerns related to groundwater degradation. The new ponds had to be made as liquidtight as practical to prevent further water degradation and to allow the existing problem to be corrected and eventually eliminated. Because of the importance of seepage control, the lining system designed for the tailings pond received very close scrutiny from the owners, the designers, and the various regulatory agencies involved in reviewing and licensing the project.

The reclamation of the existing tailings ponds and the existing mill was a primary consideration in the selection of Canon City as the new mill site. The problems with seepage from the existing unlined tailings ponds required corrective action. By having a new pond of high integrity available, solutions and slurries from the existing operation could be transferred into the new impoundment where they would be safely contained. The new impoundment is thus the key feature

in the reclamation of the existing mill area and tailings ponds.

Because of the proximity of the mill to Canon City, and because of topographic and geological conditions and the non-availability of additional suitable land, no satisfactory site off the property owned by Cotter Corporation was available. Thus, it was decided to construct the new tailings impoundment on the section of land that they already owned.

Topographically, the site is a northerly-drained alluvial valley, bounded by steep sandstone ridges on the east, southwest and northwest. Geologically, the mill and tailings ponds appear to be well sited, as they are in the middle of the bowl formed by the Chandler syncline, the axis of which bisects the project site. The surface bedrock unit underlying the tailings areas is the Poison Canyon Formation, which is some 250 m (800 feet) thick. It is composed primarily of sandstone interbedded with shales and some conglomerates. Core hole data at the site indicates interlensing of the different layers. Joints are primarily found only in sandstone and usually terminate at major bedding surfaces. Fracture frequencies are variable but, according to the core hole data, they appear to diminish considerably with depth. Figure II-2 shows a geologic cross section of the area.

Some 300 m (1,000 feet) below ground surface of the site are coal workings, mined out between 1908 and 1934. The coal seam, which averages 1.5 m (5 feet) in thickness, was mined by conventional room and pillar methods. Studies conducted during the tailings dam design indicate that collapse of the old workings would not cause detrimental subsidence at the surface.

Probably the most critical aspects of the site were the hydrogeological characteristics of the basin and the permeability of the basin area (see Figure II-1 for general site layout).

These were extensively investigated by field drilling and testing programs. Water injection tests in the exploratory core holes on the eastern flank of the retention basin, along the easterly hogback ridge, showed very high permeabilities. In most cases, all the drill water was lost in the holes. These high water losses were due to large, open fractures. However, in the central and western pond areas, the great majority of the injection tests indicated low permeability conditions. Most of the testing in these areas showed no water loss during the injection tests. However, pumpout tests conducted in observation wells downgradient of the existing ponds conflicted with the results of injection tests in the central and western pond area. The pumpout tests showed permeability values several orders of magnitude greater than did the injection tests. Furthermore, observations at cluster wells indicated that seepage flow from the existing pond is controlled by fractures or joints in the rock and this fracturing is erratic and complex.

Broadly, the results of this testing program were interpreted to mean that the eastern flank of the proposed new retention basin, where the permeability was high, would, without doubt, require lining. For the rest of the basin, the two basic data sources were in conflict. The results of the injection tests suggested that a lining would not be required, while the results of the pump tests in the wells downstream of the existing pond indicated that the lining of

FIGURE II-2

SITE CROSS SECTION

FIGURE II-3

TYPICAL MAIN DAM SECTION

the entire basin would be appropriate. After careful review of all the available information, and of the risks and liabilities involved, the Cotter Corporation decided it would be prudent and in everyone's best interests to provide a high quality lining system for the entire pond.

Selected Disposal System

Because of the topographic and geologic constraints on the property, below-grade disposal was not practical. The selected design is an above-grade disposal system consisting of zoned earth embank ments, a sophisticated lining system for the impoundment area, subdrains below the liner, and tailings dewatering drains above the liner. An idealized section is shown on Figure II-3.

The foundations for the embankments and lined impoundment areas are excavated to, or into, bedrock. As shown on Figure II-3, the embankments have an upstream sloping clay core, backed by a continuous sloping drain and a horizontal drain in the valley area. The portion of the embankment downstream of the sloping drain consists primarily of random fill. The lining system consists of three layers--a compacted 0.46 m (18-inch) clay subliner, a Hypalon membrane liner, and a 0.30 m (12-inch) soil cover. The clay subliner is provided as a cushion for the Hypalon to prevent rock perforating the membrane and to act as a secondary liner in case the membrane is inadvertently perforated. The Hypalon thickness varies from 0.91 mm (36 mils) for the shallower areas to 1.14 mm (45 mils) for the mid-depths, to 1.52 mm (60 mils) for the greater depths. The membrane liner has a reinforcing fabric scrim. The 0.30 m (12-inch) soil cover is provided to protect the Hypalon until it is covered by tailings.

The underdrain system consists of trenches excavated into bedrock, PVC pipe and gravel backfill. The purpose of the underdrains is to collect seepage emanating from areas of the bedrock and transport the collected seepage beyond the toe of the dam so that there is not a buildup of hydrostatic pressures that could displace the liner.

To futher reduce concerns about seepage over the very long term (i.e. after reclamation), the regulatory agencies requested that there be included a system to dewater the tailings to the greatest extent practical after the pond is decommissioned. Dewatering the tailings reduces the criticality of the lining system in long term containment of the waste. The dewatering system selected consists of a network of finger drains installed on top of the lining as shown on Figures II-4 and II-5. The dewatering system is to function only during reclamation and after the free water in the ponds has evaporated.

The pH is adjusted in the mill from 1.7 to 4.2. Raising the pH has the following benefits: (1) Reduces the concentration of contaminants in the liquid; hence, decreasing the potential for contamination by seepage. (2) Reduces the potential for precipitates clogging the dewatering drains. (3) Reduces precipitates covering surface of tailings after evaporation and reduces problems of placing reclamation cover. Costs for raising the pH are not included in this study.

System Quantities and Costs

The disposal system was designed to be constructed in stages. The ultimate height of the dam will be approximately 35 m (115 feet) with

FIGURE II-4

TAILINGS DEWATERING DRAINS
LAYOUT PLAN

FIGURE II-5

TAILINGS DEWATERING DRAINS
DETAILS

a crest length of about 1524 m (5,000 feet) and a tailings storage capacity of about 9 250 000 m^3 (7,500 acre-feet). The first stage embankment is 31 m (101 feet) high, has a crest length of 1497 m (4,910 feet).

The total tailings solids storage capacity of the first stage impoundments is 3 million m^3 (2,400 acre feet). The first stage tailings storage will provide for approximately 3.4 million tonnes (3.8 million tons) of ore. Construction of the first stage tailings disposal facilities commenced in the summer of 1978 and was completed in 1979. Transfer of liquids from the old tailings impoundments began in the fall of 1979 and the new mill started operating in September 1979, with the disposal of tailings in the new main impoundment at that time.

Mountain States Engineers were the designers and constructors for the mill. Wahler Associates designed the tailings disposal facilities and Stafford Construction Co., served as the construction subcontractor for the earthwork.

All earthwork materials for the embankments and liners were derived from the reservoir area and an area downstream of the dam except for sands and gravels for the various drains. Sand and gravels came from a commercial plant located near Canon City.

The first stage main and secondary embankments consisted of about 2.2 million m^3 (2.9 million cubic yards) of fill. Including clearing, grubbing, stripping, foundation preparation, embankment materials procurement and placement, and elimination of two old tailings ponds, the first stage embankments costs were about $13,000,000, which is an average of $5.86 per m^3 ($4.48 per cubic yard) of fill.

There were about 3960 m (13,000 lineal feet) of subdrains installed at a total cost of $190,000, or $47.97 per m ($14.62 per foot) of subdrain.

There were 623,000 m^2 (154 acres) of lining installed for a total cost of $5,300,000, including subliner, membrane liner, and cover. This is a cost of $8.50 per m^2 ($0.79 per square-foot) of liner.

The tailings dewatering drains consisted of 8930 m (29,300 lineal feet) of drains and two sumps for installation of pumps. The total cost of the first stage tailings dewatering system was $303,000, for an average cost of $33.93 per m ($10.34 per lineal foot) of drain.

Construction of the remaining stages will provide 6.3 million m^3 (5,100 acre-feet) of additional storage. Data for storage provided by second stage construction and total storage are presented in Table II-1.

TABLE II-1

Future Stages and Total Tailings Storage Capacities

Future Stages		Total

INTRODUCTION

The Denison uranium mine was discovered in 1954 on the west side of Quirke Lake 11 miles north of the present town of Elliot Lake. The 120 million ton ore deposit has a grade of 2.78 lbs U_3O_8/st (1.18 kg U_3O_8/t). Production started at 5450 mt/d in 1957. By 1979 the Denison Mine had produced about 90 million lbs of U_3O_8. This gives an idea of the magnitude of the tailings disposal challenge - Some 25 million tons of tailings have already been disposed of, with another 100 million or so to go.

Several interesting aspects of water management were identified at the Denison operations. Four of these are of particular interest and are a shared problem with other large uranium mines in the area:

1) Macro water recycling and management for the mine, mill, tailings, townsite and lake system.

2) Disposing of hundreds of millions of tons of tailings containing 2-4% pyrite to handle the acid mine drainage challenge.

3) Removal of radium and other radionuclides from tailings decant water.

4) Limitations on use of recycled minewater for dust suppression underground.

5) Anaerobic underground sewage treatment system.

6) Underground leaching of uranium from mine stopes.

LOCATION — 11 miles north of Elliot Lake north of Lake Huron in Ontario.

CLIMATE — Mild damp summers, frozen winters with snowfall. The area has net precipitation over evaporation.

TOPOGRAPHY — Rolling hillsides with an intricate system of lakes and streams.

PROCESS

Ore is crushed and ground, then subjected to a conventional sulfuric acid leach followed by ion exchange. $NaOCl_4$ and recycled iron cake are used as oxidants in the leaching process. Ammonia is used to precipitate uranium from the eluate as ammonium di uranate (ADU). Nitric acid is used as the eluant to elute uranium from the loaded resin.

From a water management standpoint the use of ammonia could be expected to result in ammonia in the discharge to the lake which might be detrimental to the aquatic ecosystem.

The simplified process flowsheet is shown below.

WATER BALANCE

A water balance showing how water use is distributed to the various operating units at Denison Mines is shown. The numbers are in Imperial gallons per minute.

WATER UTILIZATION AND RECYCLE

The main source of water for the mines and mill at Denison Mines is Quirke Lake. The following volumes of water are used for the mines and mill from Quirke Lake.

To No. 1 Shaft area :	505 Igpm	3,300 m^3/d
No. 2 Shaft area :	1453 Igpm	9,500 m^3/d
Concentrator area :	2261 Igpm	14,800 m^3/d
Total	4219 Igpm	27,600 m^3/d

Gross water use works out to 5.1 m^3 water/ton ore based on 5400 mtpd ore throughput. Of this gross water intake, 1100 Igpm (7,200 m^3/d) that was used for compressor cooling is returned directly to Quirke Lake. Of the 3150 Igpm (20,600 m^3/d) pumped to the tailings pond with tailings, presumably 40% or so finds its way back to the Quirke Lake thereby constituting a macro recycle, but it is not recycled to the process directly.

The mine

The Denison mine, more than 6,400 acres (2,600 hectares) in surface area, is located on the north limb of the famous Quirke Lake syncline. The main ore zone, consisting of the two uranium-bearing conglomerate beds, dips from north to south at an average inclination of 20 degrees. At the upper end it lies 550 feet (168 metres) below the surface and deepens to 3,100 feet (945 metres) at the south property boundary.

In many areas mining of the main ore zone is carried out over the entire section comprising the two conglomerate beds and the interbedded quartzite. In other areas the conglomerate beds are selectively mined, depending on the thickness of the interbedded quartzite. Minor undulations occur throughout the orebody and faults, dykes and sills have been encountered in several locations.

The three shallower reefs above the main ore zone will be mined sequentially when required.

The uranium-bearing conglomerate beds are reached by two main vertical shafts, approximately 2,600 feet (800 metres) apart. The first shaft gives access to the orebody at the 1,600 foot (488 metres) level and the second shaft, farther down-dip, intersects the main ore zone at the 2,465 foot (752 metres) horizon. The mining method requires only one main underground station at each shaft.

Two other shafts at the east end of the property, formerly part of the neighboring Can-Met mine, have been connected with the Denison underground workings for ventilation purposes. The two Stanrock shafts eventually will be connected to the main Denison underground workings.

Water management practice at Denison Mines Ltd. and other Ontario uranium operations contrasts with that at Rössing Uranium Ltd. in the Namib Desert which uses about one fifth the amount of water or less, per ton of ore treated.

In the metallurgical treatment process, water is recycled primarily to segregate the acid and neutral circuits to save corrosion and reduce overall acid consumption. In-plant water recycling loops are as follows:

1) Neutral water added to the grinding circuit is recovered from the ground pulp ahead of acid addition for leaching, by thickening and filtration, and is recycled to the grinding circuit. Dewatered pulp is repulped with recycled acid barrens.

2) Acid solutions are recycled after leaching, solid-liquid separation and ion exchange when barrens are recycled to the repulper at the head of the leach train. In this way acid consumption is reduced.

3) Eluate, after purification and precipitation of the ADU product, is decanted and recycled as fresh eluate after addition of nitric acid.

4) Compressor cooling water is used as glandwater.

5) Compressor water is used in spraybars for the second step filtration of leached pulp to wash tailings. This use of compressor water replaced one application of fresh water. Barrens are used for primary filtration wash.

6) 866 Igpm (5700 m^3/d) underground minewater is recycled to the metallurgical process.

FRESH WATER FROM QUIRKE LAKE IS ADDED FOR:

1. Underground mining operations for dust suppression.

2. Compressor cooling

3. Boiler water for steam

4. Pump glands

NON-RECYCLABLE WATER

1) Since nitric acid is used in the elution circuit, the use of barrens after uranium precipitation in the front end of the process would be a problem as the contained nitrates could interfere with the strong base ion exchange adsorption process.

2) Water is required for dust suppression in the quartz rich underground mine. The Ontario Ministry of Labor does not allow the recycle of water underground. They are worried about increased silicosis risk if recycled water containing silica is atomised in the stopes. Silica levels in the water are less than 10 ppm (total suspended solids). However, with high gypsum levels which would result from recycling of the water, the nozzles could become encrusted and dust suppression waterflow might is choke off. Also, if water is recycled and gypsum levels build up, this could cause a problem if mineworkers drink the water.

REGULATORY FRAMEWORK

Mining in Canada is controlled by the Federal Metal Mines Regulations which were promulgated under the Canada Fisheries Act. The Provincial government has a Mininstry of the Environment which can enter into an agreement with the Federal Government to apply the Fisheries Act to which provincial regulations can be added. Ontario has elected not to enter into this agreement. Consequently in Ontario the Mininstry of the Environment (MOE), does not have regulatory authority over metal mines. MOE does, however, review all mining operations, set environmental objectives, criteria etc. The MOE regional director has the authority to write rules on a case by case basis, and can insert some control on a case by case basis via an order on effluents that affect receiving waters.

Uranium mines fall under the ultimate jurisdiction of the Atomic Energy Control Board as set out in the Atomic Energy Control Act. The AECB can develop regulations to control uranium mines and mills or it can do so through issuing individual site specific licenses which is the approach that it has elected to use.

EFFLUENT LIMITS

Denison Mines Ltd. must comply with two sets of regulations - The AECB effluent discharge limits and the Federal Fisheries Act regulated by Environment Canada.

	AECB License Grab Sample (ppm)	Federal Metal Mine Regulations	DENISON MOE Objective
pH	6.5-9.5		
Cu Max	0.6		
Ni Max	1.0		
Pb Max	0.4		
Zn Max	1.0		
Cumulative Zn, Pb, Cu, Max	1.0		
Suspended Solids	15.0 (grab)		
	7.0 (Monthly Ave)		
Radium 226 pCi/l	5.0 (Monthly Ave)	10 pCi/l Monthly Ave	3.0 pCi/l
		5 pCi/l Annual Ave	
		10 pCi/l Composite	
		15 pCi/l Grab Sample	

The Federal drinking water objective for Radium-226 has been set at 27 pCi/l which means the level required for mine water discharge is very much stricter than drinking water levels for reasons not explained.

PLANT RUNOFF

Plant runoff from the mill area drains into the same catchment as the tailings drainage basin including the stormwater sewer.

Ore stockpiles are in the open, but normally coarse ore is not stockpiled. There is an unlined area that can be used for ore stockpiles if needed. This is located in the Waste Management Catchment area. Fine ore bins for the rod mills are covered. ROM feed for the SAG mill is also in a covered bin.

All water draining from these areas is collected, settled and treated with $BaCl_2$ for radium removal.

SEWAGE

The septic tank system is employed with effluent going to the tailings area. Septic tank sludges are pumped to the tailings dams.

Previously chemical toilets were used underground and the waste was dumped with the mill tailings. Now an anaerobic toilet sewage system is employed underground. The

overflow from the anaerobic system goes to the minewater mine-sump. The anaerobic sewage plant was supplied by Fitzpatrick Ltd., Sault Ste. Marie, Ontario.

MINEWATER

During 1983 minewater was pumped from underground at an average rate of 70 l/s (924 lgpm, 6048 m^3/d) and used in the grinding circuit. This water is used for underground leaching of uranium from the stopes at the same time as suppressing dust. No oxidant is added nor nutrients. Composition of the minewater is in mg/l is:

pH	2.7
Fe	300 ppm
Zn	4.5
Cu	1.28
Ni	0.84
Mn	1.9
Pb	5.05
$SO_4^=$	2050
Ca	176
Cl^-	113
NH_4^+ as N	47
NO_3^- as N	60
K^+	99.6
Mg	20
U_3O_8	104
Ra-226 Dissolved	40 pCi/l
Ra-226 Total	60 pCi/l

Underground leach solutions goes to the mine sump with all other minewater and is pumped to the surface after pH adjustment.

TAILINGS DECANT SOLUTION - FINAL EFFLUENT

Tailings pulps are neutralized to pH 8.3 and after decanting and treatment for radium removal, a final effluent is discharged at an average flowrate of 272 l/s (23,500 m^3/d, 3500 pgm) with the following composition compared with the regulatory limit:

	Tailings Solution after Neutralization	Final Effluent Composition	DENISON Regulatory Limit
pH	8.1	8.2	6.5-9.5
Radium (pCi/l)	1411	3.3	5,10 pCi/l
NH_3 (N)	97	60	No limit
NO_3^- (N)	143	81	No limit
TDS	3800	2852	No limit
Mg	48	24.8	No limit
SO_4	1750	1572	No limit
Cu	0.04	0.02	0.6 } combined max 1.0 ppm
Pb	0.25	0.109	0.4 } combined max 1.0 ppm
Zn	0.01	0.02	1.0 } combined max 1.0 ppm
Ni	0.01	0.12*	1.0 } combined max 1.0 ppm
Co	0.02	L T 0.02	
Mn	0.01	0.44*	
Ca	480	509	
K	146	80	
Cl	159	110	
Fe	0.06	0.35	
Na	396	87	
Kjiedhahl N	-	15	-
Ba	-	L T 0.11	No limit
PO_4^{3-} as P	-	0.09	-
Suspended Solids	-	2.5	15
Alkalinity as $CaCO_3$	-	46	-
U_3O_8	-	0.1 ppm	-

TAILINGS DISPOSAL

Tailings pulps are neutralized with lime to pH 8.2 and pumped to the tailings dam which is the first impoundment in the tailings system.

The biggest challenge facing uranium mill tailings disposal is the acid mine drainage problem that results from the pyrite content of the tailings. The acid generated is harmful to the water system in itself but also leaches out other radionuclides, for example, thorium and lead 210. A satisfactory long term method of disposing of pyrite containing tailings is needed.

Denison tailings are ground to 50% minus 200 mesh. Tailings at Denison and the Stanrock property which was acquired after it shut down, are disposed of both in above-ground

tailings ponds and underwater in lakes. In all cases so far the tailings generate acid mine drainage which has to be neutralized by lime addition after decanting.

Decanted tailings effluent is treated with $BaCl_2$ to precipitate radium-226 as discussed below.

Denison has found that when pyrite bearing tailings are disposed of under water, the pyrite will oxidize chemically only if water passes through the pond. Since all tailings dams leak, oxidation of pyrite is inevitable. However, chemical oxidation of pyrite will be slower than in the typical above ground tailings dams with their seepage and runoff.

The use of subaerial layered impoundments in which the tailings never become saturated with water and in which the tailings are emplaced in impermeable layers has been tested with success at Key Lake Uranium where permeabilities as low as 10^{-7} to 10^{-8} cm/sec are achieved. This process is labor intensive and expensive for low grade ores. The same applies to the South African technique of dry tailings disposal with underdrains, which is more applicable in the Witwatersrand climate.

Another possibility considered by Denison is the use of accelerated oxidation and neutralization before emplacement of the tailings. This was found to require too much lime. However, it potentially yields an inert tailings that do not require perpetual treatment. It is noted that sulfuric acid is purchased for the leaching of uranium. Processes that generate sulfuric acid from the pyrite in the ore are available either by pressure oxidation of the ore or by floating pyrite from the ore and roasting it. Either of these represent a way to reduce the acid mine drainage problems at Denison Mines Ltd. but would require extra capital and operating costs and would be ruled out in the currently depressed uranium market.

The Robinsky thickened tailings disposal method was tested on an experimental 12,000 t pile with a 5% slope. Over a 2 year period little erosion was noted and vertical permeability was reduced. The test heap was seeded and fertilized without any mechanical problems, but massive seedkill occurred in places. Slopes are steeper on thickened tailings and runoff is faster. The material is kept homogenous and does not filter well because of the way slimes are mixed with the coarser particles. Thickened tailings with only 25% moisture can be achieved, and the remaining water can be neutralized and disposed of in the same pond. Thickened tailings achieve these characteristics by preventing separation of sand/slimes in the pond.

Covering the tailings with compost to establish plant growth in some cases unexpectedly enhanced the rate of oxidation and was not effective in all cases. It is fair to conclude that the optimum solution to disposal of Elliot Lake uranium tailings has still be be found. It has been the subject of a massive research program funded by the Federal Government. CANMET is carrying out excellent accelerated tailings oxidation tests in Atlanra in which a bactorstat has been added, seeding with fertilzer, compost cover at different thicknesses are compared with disposal as received. More information is available from:

CANMET
555 Booth Street
Ottawa Ontario K1A 0G1
(613) 995-4194
Contact: Eddie Joe, Gordon M. Ritcey

A 10:1 acceleration rate has been achieved in the test. The leach test with the 30 cm compost cover resulted in pH 5 seepage indicating minimal acid generation which is encouraging.

RADIUM REMOVAL

Denison has found that radium in the final effluent is a function of the volume of effluent. Radium dissolves as a function of the amount of water in the mill. If ore is washed in fresh water, radium continues to dissolve from the matrix, so the amount of water is reduced by recycling.

In the solids fraction of mill tailings there is an average of 256 pCi/g radium. The water in the mill tailings after being neutralized contains 1411 pCi/l radium i.e., 1.4 pCi/g and 4000 mg/l TDS, mostly as $CaSO_4$. Before $BaCl_2$ addition, soluble radium in the decanted tailings effluent runs about 370 pCi/l which indicates that a lot of the radium gets left behind tied up in gypsum as the tailings are neutralized. After a few weeks aging, the dissolved radium in the pulp drops to 125 pCi/l as it attaches to solid particles. After about twenty years aging if the tailings are not altered chemically radium in the saturated pore solution will have dropped to 120 pCi/l.

The behavior of radium in tailings solutions under various conditions has been intensively studied by:

Al J. Vivyurka
Senior Environmental Engineer
Rio Algom Ltd.
P. O. Box 1500
Elliott Lake, Ontario
Canada P5A 2K1
Telephone: (705) 461-2518
Telex: 067-7338

After $BaCl_2$ treatment of the tailings pulp, radium drops to 3.3 pCi/l average. The ratio of total to soluble radium varies depending on conditions, turbulence, etc. Radium is settled out as coprecipitated $BaRaSO_4$ in which radium levels typically fall in the range 500-5000 pCi/g.

According to Mr. Chakravatti the amount of radium in the residual effluent is almost independent of the barium chloride dosage. It depends on how it is contacted with $BaCl_2$, i.e., contact time, settling capacity, pH etc. At high pH the flocs don't settle as well as at low pH. Also, the higher the sulfate concentration in the solution, the more effective the radium removal process. It was found that by adding $BaCl_2$ much more $SO_4^=$ and gypsum are precipitated than would be expected.

Concentration of radium in the sludge precipitated at higher pH is lowered by gypsum that precipitates too. In such cases the radium level in the sludge can be significantly diluted by the gypsum and may be in the hundreds of pCi/g rather than in the thousands of pCi/g. If $BaCl_2$ is added to a slightly acid effluent, radium precipitation works better than adding $BaCl_2$ to high pH effluents.

Precipitation of $BaSO_4$ is pH dependent like all sulfate precipitation reactions. When lime is added to the solution, a range of species such as $CaSO_4$, $BaSO_4$ and Ca-$BaSO_4$ will precipitate. The precipitation on addition of $BaCl_2$ goes faster at pH5-6 for some reason than when $BaCl_2$ is added to high pH solutions from which mainly $BaSO_4$ would precipitate.

The result of lower pH $BaCl_2$ is:

1) More radium is precipitated
2) Ba-Ra-SO_4 precipitates in a bigger volume of precipitate

Denison Mines adds $BaCl_2$ to the effluent at pH 8 and does not have a subsequent pH adjustment like Rio Algom's Panel operation. Denison achieves a final effluent with 3pCi/l Ra or less.

AMMONIA

The Denison final effluent runs around 60 ppm NH_3. As water recirculates from the tailings decant dam to the huge volume in Quirke Lake there is such a long residence time that some nitrification of ammonia occurs which reduces the ammonia level. During ammonia oxidation hydrogen ions are generated which drops the pH. At the higher levels in Quirke Lake the rate of NH_3 oxidation is faster and this brings the pH back down again, by the reaction

$$NH_4^+ + 0_2 + = NO_3^- + H^+ \text{ (unbalanced)}$$

CHAROPHYCEAE

In this way ammonia tends to stabilize the pH of the lake.

The main source of NH_3 in the effluents is from its use in precipitating ADU. NH_3 in effluent could be avoided by converting to magnesium oxide for uranium precipitation as recommended by MOE. However, Denison has a Mg penalty clause in their sales contract for yellowcake. It was felt that the inventory of ammonia in the lake was already so high that there would not be a marked reduction in $[NH_4^+]$ in the lake for a long time, i.e. whaterever damage will be done has already been done.

Peroxide precipitation of uranium would avoid the magnesium contamination of product, but was ruled out because of the extra expense.

ECOLOGICAL ENGINEERING

For some time now Denison Mines Ltd. and has Algom Ltd. have hosted botanical research into finding various aquatic plants that will grow in the low and high pH effluent and tailings environment found in the tailings and decant plant. This work has been carried out by:

Boojum Research Ltd.
26 Geneva Avenue
Toronto, Ontario M5A 2J8
Telephone: (416) 922-9002
Contact: Margaret Kalin, PhD

This work aims to identify and grow plants that can survive in the severe (for plants) pH conditions in the Elliot Lake tailings and effluent environment. Some species will hopefully prove useful either as a means of removing metal ions from water or by creating a layer of organic material on the solids-aqueous interface of submerged tailings which would create a reducing environment that will prevent further oxidation of pyrite in the layers of tailings below. The work undertaken to date has been exploratory and no firm conclusions can be drawn yet. One very interesting species of aquatic macro algae known as Chara is one on which researchers' early hopes have been placed.

CONCLUSIONS

1. The acid mine drainage problem from pyrite bearing Elliot Lake uranium tailings is far from resolved. A tour of several tailings sites brings home the magnitude of this problem which will arise on closure of this and other similar mines. Will perpetual treatment be required?

2. $BaCl_2$ addition is very effective for removal of radium from effluent solutions and works best at pH 5-6 with very small doses.

3. In areas such as Elliot Lake where water is abundantly available, this is reflected in the water usage of an overall 8 m^3 per ton ore treated (including mining).

4. Denison Mines practices an interesting form of in situ leaching in which incremental uranium is recovered from the stopes by irrigating them with water. Natural pyrite oxidation drops the pH to leach uranium to 100 plus ppm.

DATE OF VISIT 7 August 1984 to Key Lake Mining Offices

INTRODUCTION

Key Lake Mining is one of the very high grade uranium ore mines in Canada. Several interesting features have been observed:

1. The ore contains nickel, arsenic, radium etc. which must be taken into account in water management and environmental control.

2 Bentonite stabilized soil has been used as the main lining for the tailings pond which is also covered with a 3 ft thick sand layer over a drainage system to collect and remove solutions.

3. Sub-aerial tailings disposal is practised. Decant is recycled to the plant. Before it reaches the plant, however, arsenic and nickel are removed. An interesting oxidation and precipitation procedure is described as well as an interesting way to achieve a high precipitate sludge density.

4. The operation employs a two stage leach, the second of which is pressurized with oxygen addition. The plant started up using air as oxidant in the pressure leach but it was found that the high arsenic ores needed O_2 for good uranium leach recovery.

5. Raffinate is kept separate and is treated by lime precipitation. An expensive effluent storage and management step has been required employing five lined

monitoring ponds. Each day's effluent, after treatment, is collected in a pond while it is sampled and analyzed. If it meets the effluent limits, it is released to the lake, if not, it is retreated.

6. Lining failure in the monitor ponds even before they were filled with effluent provides and interesting case study on membrane linings. The membranes in this case were underlain by bentonite stabilized soil as a safety measure.

7. The high grade of the deposit economically justifies expensive water treatment and tailings impoundment measures employed including the installation of utilidors, concrete tunnels through which all slurry and solution lines are channelled.

8. Precipitate density in the water treatment step is higher than expected in the design. The Lamella thickener sumps had to be modified to be able to handle the sludges.

9. Gypsum scaling problems have caused a severe problem requiring replacement of buried pipelines which could possibly have been avoided by installing flexible above-ground lines to start with.

10. The Radium precipitation procedure followed at Key Lake is very fast and accomplishes in hours what in other mines, such as Elliott Lake and Rabbit Lake, takes days or weeks.

11. Barium chloride addition to semi-treated effluent results in a further reduction in arsenic levels to less than 0.01 ppm As in the effluent. Precise reasons for this excellent reduction are not completely clear, but it does occur.

12. In January 1984 a water reservoir at Key Lake Mining overflowed while under ice cover resulting in a public outcry, even though no damage was done. When a dam overflows under its ice and snow cover, the leakage is invisible at the time. Special measures have been adopted to prevent a recurrence, which would be useful at other operations in the similar climates.

13. Exceptional measures have been incorporated in the design to reduce the risk of leakage of undesirable metals, reagents and radioactive isotopes to the environment.

Although a small mine at 700 tpd ore, a total of 21,000 tons per day of wasterock must be moved. Based on production of 12 million lbs/year U_3O_8 Key Lake must be one of the largest if not the largest uranium producer in North America.

OWNERSHIP Key Lake Mining Corporation, the operating company is owned by:

Saskatchewan Mining & Development Organization	50 %
Uranerz	33.3%
Eldorado Resources	16.6%

STARTUP October 1983. The first Key Lake ore deposit was discovered in 1975.

PLANT CAPACITY 700 tons per day ore mined; 12mm lbs U_3O_8/year.

MINING RATE 30:1 Mining Ratio

CAPITAL COST $450 million investment

CLIMATE
Extremely cold subarctic winters
Evaporation is almost equal to precipitation
Temperatures to minus 40°C in winter
Extended period of snowcover

ORE TYPE

The uranium is associated with arsenosulfides mostly a nickel arsenosulfide $NiAsS_2$ gersdorffite. The ore is clay rich and extremely variable in grade (0.01% U_3O_8 to over 20% U_3O_8).

WASTEROCK Inert material low or devoid of sulfides.

PROCESS

Because of the very high grade of ore, high leach recoveries of 99% plus are required. To achieve this a 2-stage sulfuric acid leach is needed using oxygen as oxidant in the second stage leach. The final metallurgical process was developed by:

Sherritt-Gordon Mines Ltd.
Fort Saskatchewan, Alberta
Canada T8L 2P2

Telephone (403) 988-6911
Contacts: Herb Veltman, Director
D. Robert Weir, Manager Process Research
Roman Berezowsky, Senior Research Metallurgist

An excellent detailed account of the process development for Key Lake is provided by CLARKE et al. (1980).

KEY LAKE MINING COMPANY

AFTER CCD

Uranium is recovered by SX followed by ammonium sulfate strip. Overall plant recovery of 97% is achieved. Ammonia is recovered for reuse using a lime-boil process primarily as an environmental control measure.

ACID PLANT

A small Krebs sulfuric acid plant generates 200 tpd H_2SO_4 from sulfur feed.

ADDITIONAL INFORMATION

1) Additional detailed information on the Key Lake Mining operation can be found in a review document at the Atomic Energy Control Board, Ottawa.
2) Canadian Mining Journal, June 1984
3) Canadian Chemical Processing, April/May 1984 pp. 20-26

PLANT CONSTRUCTION

Wright Engineers, Vancouver, were the plant engineers.
Commonwealth Construction, construction managers.

TAILINGS POND CONSTRUCTION

The soil stabilized bentonite seal was installed by a subcontractor. 12 Kg Bentonite per m^2 was spread and then mixed in to a depth of 1 ft. The mix is believed to have been moistened and compacted but this detail is not certain. The bentonite stabilized soil achieves a satisfactory low permeability.

The bentonite stabilized lining is covered with a 3' layer of porous sand covering a system of perforated pipe to drain any fluids from the sloped lining. The tailings impoundment floor is sloped at ½ - 1% in two directions to move drainage to a sump.

Bentonite stabilized soil linings of the tailings pond and the five monitor ponds were proposed by Knight and Piezold, Geotechnic Consultants in Vancouver, who were also consultants to the project:

Knight & Piezold
409 Granville
Vancouver, BC V6C 1T2
(604) 685-0543

R. Bruce Knight - Partner

TAILINGS DISPOSAL

The tailings are pumped to a permanent storage pond where they are spread in sequenced 100 mm (4") layers which become hardened and almost impermeable. The pond itself is underlain with a sealing layer of till and bentonite. A network of pipes under the tailings with upcomers collects supernatant water which is returned to the bulk-neutralization plant. Upon decommissioning of the project, the tails will be covered with a surface sealing layer. The drainage system will remain in place so that any seepage can be monitored.

The thin layer dry tailings disposal concept also known as "sub-aerial" was also proposed for this project by Knight & Piezold. The tailings are spread over paddocked sections of the tailings pond in thin layers. Solution is decanted from each layer and removed either for reuse as recycle or to be treated and discharged. After being decanted and dried the surface layer of tailings shrinks and cracks. The cracks are however filled by the next layer of pulp. To achieve this the tailings pulp is spread at a relatively low pulp density of 35-40% solids which allows even spreading and the desired particle size segregation in each layer.

The tailings are limed to pH 11 before being pumped to the tailings pond after blending of water treatment plant sludges consisting of metal precipitates with an excess of lime.

Tailings pulp at 35-40% solids are spread over the previous decanted surface in a 10 cm (4") thick layer and decanted. On drying the top layer shrinks and cracks.

The layered dry tailings system results in material with a low permeability of 10^{-9} to 10^{-11} which is remarkable. The system is compact and in any case is protected by the sand layer with underdrains and a low permeability bentonite stabilized soil lining. If the system consistently performs as described the design would appear to be over-conservative and it is conceivable that it future modification could safely reduce costs.

The dry laminated tailings system was pilot tested at Sherritt-Gordon with 7 layers of tailings under simulated conditions. The paper by CLARKE et al. (1980) discusses how these tests were performed.

Sherritt-Gordon also pilot tested the pressure leaching process employed at Key Lake Mines, an interesting aspect which nonetheless is not a focal point of this study except from the point of view of its impact on dissolved metal concentrations in the leached pulp which are greatly enhanced by pressure leaching, particularly arsenic when oxygen is used.

In August, 1984 there were not yet enough tailings to cover the entire lined tailings area. Nor had the innovative system been applied through a whole winter.

ORE GRIND	100% minus 500 u	(35 mesh)
	45% munus 44 u	(325 mesh)

This indicates a very fine grind.

WATER CONSIDERATIONS

There are two main aspects of collecting and treating water:

Minewater

Key Lake operates two mine pits, both of which are surrounded by lakes. Both deposits were located underneath lakes that had to be drained and dewatered before the ore could be mined.

Around each mine pit there are a number of dewatering wells. Dewatering of each pit requires a constant discharge of 0.3 m^3/second (26,000 m^3d) to the lake system. This minewater has high radium levels of 30 Bacquerel (about 900 piC/l.)

(37 Millibacquerels $\underline{=}$ 1 PiC/l)

The water also contains traces of As, Ni and U_3O_8. Approximately 1200-1500 m^3/d is used as process water, but at 300 l/sec from each of 2 pits the total water to be discharged works out to over 50,000 m^3/day.

SX Raffinate

SX Raffinate is treated with lime to precipitate gypsum and metals. Thereafter the solids are settled in lamella thickeners and the decant pumped to one of five monitor ponds each with 5000 m^3 capacity, enough for about one day's storage. As soon as a pond fills it is sampled and analyzed. If it is within the regulatory limits it can be released to the lake.

During neutralization soluble arsenic is dropped to less than 0.5 ppm As.

Water after treatment is sampled and analyzed in batches. If any of the regulatory limits are exceeded the water is returned to the treatment plant.

REGULATORY LIMITS

The Atomic Energy Control Board in conjuntion with the Province of Saskatchewan have set the following limits for effluents from Key Lake. The comment was made that Saskatchewan has generally stricter limits than the AECB.

	Maximum Monthly Mean (Arithmetic)	Composite Sample	Maximum Grab Sample
As	0.5 ppm	0.75	1.0 ppm
Cu	0.3 ppm	0.45	0.6 ppm
Ra	0.37 Bq/l		
	10 PiC/l	20.0 PiC/l	30.0 PiC/l
U	0.50 ppm		
Ni	0.5 ppm	0.75	1.0 ppm
Pb	0.2 ppm	0.30	0.4 ppm
Zn	0.5 ppm	0.75	1.0 ppm
Suspended Solids	25 ppm	37.5	50.00 ppm
$NH_4^=$	30 ppm at pH between 5-7		
pH	6 min	5.5 min	5.0 min

BULK NEUTRALIZATION

All solid and liquid wastes from the Key Lake operation are treated in the bulk neutralization plant. These include the raffinate from the solvent extraction plant, underflow from the CCD thickeners and all contaminated water from the mine, shops, mill and plant site. Clean water that can be released into the environment and solid wastes, or tailings, in which contaminants are immobilized are produced.

There are four main steps in bulk neutralization: neutralization; radium removal, pH adjustment and filtering of liquids; and slurry treatment and filtering. Throughout the process, the pH must be strictly controlled to aid in the removal of solids and to fix contaminants in insoluble compounds. Microprocessor control provided by UCS No. 5 makes this possible. The pH of liquids is first raised so that metals can be precipitated. It must then be lowered to 7.0 before release into the environment.

WATER TREATMENT PLANT

Capacity	(implied 5000 m^3d	= 58 l/sec)
$BaCl_2$ consumption	20g $BaCl_2$/Kg U_3O_8	= 109 Mt/year
		= 450g $BaCl_3$ per ton ore
Lime consumption		= 130 Kg/ton ore

1) Raffinate and minewater to be treated are neutralized in four air agitated pachucas in series with flash mixers for lime addition before each pachuca. The flash mixers are fitted with propeller agitators.

2) The precipitate is settled in Axel Johnson lamella clarifiers.

3) Underflow from the clarifier is mixed with the CCD underflow i.e., with ore tailings after leaching and washing.

4) Overflow from the clarifier is mixed in the next row of flash mixers and pachucas. Lime, $BaCl_2$ are added. The pH is now 11 to precipitate Ra Ba SO_4, Ba Ra Arsenate and Mg $(OH)_2$.

5) Residual arsenic is precipitated as $Ba_3(AsO_4)_2$ which according to CLARKE et al. (1980) is much less soluble than Calcium Arsenate ($8x10^{-51}$ at 25°C) although this fact is disputed by ROBINS (1984 personal communication). Possibly, the further reduction of arsenic levels in the treated effluent is due to enhanced removal of particulates with the $BaRaSO_4$ precipitate.

KEY LAKE MINING EFFLUENT TREATMENT

6) The second stage neutralization water is next clarified in clarifier 2. The No. 2 lamella clarifier underflow is mixed with the No. 1 lamella underflow and disposed of with the CCD underflow to the tailings impoundment.

7) Overflow from lamella 2 is filtered through diatomaceous earth filters (as of July 1984 this diatomaceous earth filter was not in use as the suspended solids levels are low enough for it not to be needed.)

8) pH of treated, clarified solution is adjusted from pH 11 to pH 7 by adding H_2SO_4.

9) The treated, pH adjusted effluent water stream is next directed to one of the 5 monitor ponds (500 m^3 each). If the water quality meets the effluent standard, it is discharged. If not, it is pumped to one of the two water reservoirs (250,000 m^3 and 120,000 m^3 capacity.)

EFFLUENT QUALITY

Effluent quality as determined in the Sherritt Gordon pilot tests are shown below, indicating a very effective process.

Table
Effluent Water Quality

Element	mg/l	Element	mg/l
Aluminum	LT 0.01	Molybdenum	0.04
Arsenic	LT 0.01	Nickel	LT 0.01
Barium	LT 0.4	Phosphorus	0.14
Calcium	701	Potassium	54
Chloride	20	Selenium	LT 0.01
Chromium	0.02	Silicon	0.38
Cobalt	0.01	Sodium	55
Copper	0.01	Sulphur	640
Fluoride	2	Titanium	0.01
Iron	0.06	Uranium	0.85
Lead	LT 0.01	Vanadium	0.01
Magnesium	0.65	Zinc	LT 0.01
Manganese	LT 0.01		

LT = Less Than

The radiological composition of the final effluent achieved during the experimental program is shown in the Table below and compared with target levels for radioactive isotopes in the effluents. All targets were met.

Table
Radiological Composition of Final Effluent

Isotope	Pico Curies Per Liter Activity	MPCw
Radium 226	1.6	10
Lead 210	0.5	100
Polonium 210	0.3	700
Thorium 227	0.5	
Thorium 228	1.4	7000
Thorium 230	0.8	2000
Thorium 232	1.4	2000

These reservoirs store water which is used for process water and as feed to the treatment plant. Tailings decant water also gets directed to these reservoirs.

One of the operating surprises encountered when the plant was commissioned was that the limed precipitate settled very much faster than expected in big crystals. As a result the lamella thickener rakes were overloaded and the mechanism jammed. This problem was overcome by installing cone bottoms on the thickeners. Initially drum filters were installed with a view to dewatering the clarifier underflow sludges but these are not needed in practice.

A major advantage of the Key Lake effluent treatment system is that the indoor process is very rapid. It can be monitored and if there is a problem it can be detected and corrected much more quickly than is possible when radium is removed by adding $BaCl_2$ to a large pond with a long residence time. The water treatment plant was designed by Wright Engineers based on a Key Lake proven concept that was tested by Sherritt-Gordon Mines.

WATER IMPOUNDMENTS

The plant includes the following water impoundments:

- 5 monitor ponds to collect treated minewater plus Raffinate prior to discharge

Behaviour of Arsenic in Continuous Bulk Precipitation

Effect of pH on Terminal Arsenic Concentration After $BaCl_2$ Addition: Treatment of Bulk Precipitation Waste Waters

- 2 water reservoirs
  - plant water
  - potable water

- 1 fire fighting water pond at the mill

POND LININGS

Initially all impoundments were lined using 40 mil hypalon (1 millimeter) over bentonite stabilized soil. The monitor pond linings were installed in the summer of 1982 well before plant startup. Since the ponds are to be used intermittently with fluctuating solution levels there should have been no problem in leaving them empty.

By 1983, even before the ponds were put in use the linings delaminated and seams came loose at many spots to the extent that the lining had to be replaced.

NEW POND LININGS

The hypalon membrane was replaced by 100 mil HDPE supplied and installed by Schlegel in 1983, as described in a recent Schlegel advertisement inserted below.

Recently Columbia Impoundment Systems of Calgary, Alberta, have demonstrated an HDPE lining installation method with a double seam and air test.

LEVEL CONTROL

In January 1984 there was a spill form one of the Key Lake water reservoirs. The problem arose during winter when the reservoir was covered by snow and ice, and operators were not aware of the spill as the overflow stream was hidden from view by the snowcover. Controls are needed to detect when snowcovered impoundments are full. In this case there appears to have been no damage of consequence to the muskeg.

ENVIRONMENTAL CONTROL AUTHORITIES

Key Lake Mining is regulated by the Atomic Energy Control Board of Canada and the Saskatchewan Department of the Environment, Prince Albert, Saskatchewan.

ENVIRONMENTAL CONSULTANTS

Beak and Associates

SPECIAL ENVIRONMENTAL PROTECTION MEASURES

- $(NH_4)_2SO_4$ is employed to strip the SX organic and NH_3 to precipitate uranium thereafter.
- Yellowcake filtrate solutions have to be treated at Key Lake to recover $(NH_4)_2SO_4$ to prevent NH_4^+ discharge in the plant effluent if it were to be discharged with tailings or treated raffinate solutions. Sherritt-Gordon Mines Ltd. designed the $(NH_4)_2SO_4$ recovery plant.
- 1 m wide X 50 cm deep concrete "utilidors" are installed to contain any breaks in the tailings line. The utilidor is fitted with a sump to contain the volume of tailings that could leak into it in the event of a break. The utilidors are covered and heated in winter.
- A 1700 m utilidor is installed from the ore crushing plant to the main metallurgical plant. It carries ten pipes.

ARE GEOTEXTILES NECESSARY WITH THICK LINERS?

Puncture and Tear Resistance Not Necessarily Improved

POLLUTION ENGINEERING magazine in its November 1983 issue reported the results of a study made by a geotextile manufacturer in which various geomembranes were evaluated for their puncture and tear resistance, alone and then with the addition of three different grades of geotextile. A laboratory procedure was developed to simulate the effects of equipment moving over the geomembrane. According to the magazine article, "Although there were major differences in the resistance of various membranes, the geotextile fabric offered significant protection from aggregate cutting, puncture and abrasion . . . "[1]

Is a geotextile always necessary for cushioning and protection against puncture and tear? The incorporation of a geotextile with a geomembrane may serve many important purposes, including filtration, soil stability, overburden stabilization, drainage, gas ventilation and so forth. But an appropriately thick liner, which Schlegel Lining Technology defines as 2.0 mm (80 mil) or more, is usually thick enough to resist both high and low speed puncture and resultant tear without the expense of

Continued on page 2.

World's largest uranium mine lines reservoirs with 100 mil HDPE

In the summer of 1983, officials of Key Lake Mining Corporation (KLMC) were faced with the task of having to reline two reservoirs and five monitoring ponds. These are sited adjacent to the mill and tailings deposition area on surficial materials of glacial till, sand and gravel.

Key Lake Mine will eventually be the largest uranium mining/milling complex in the world. Ore is extracted from two discrete deposits by open pit mining methods. The mill is designed to process 780 tons of ore per day using conventional separation and extraction techniques.

The Key Lake Mine site is located 400 miles north of Saskatoon, in Saskatchewan, Canada. Severe winters, featuring temperatures as low as −40°F, are the norm.

The purpose of the reservoirs is to store contaminated water from the open pit and ore stockpile areas. The first reservoir, with a capacity of 240,000 m^3, holds mine water and site and stockpile runoff. All runoff from the ore stockpiles, the open pits and the mill is considered contaminated, and is collected and stored in this reservoir. This reservoir also serves as a source of process water for the mill, as no free water is ordinarily introduced into the milling process, other than what is collected by dewatering. This reservoir was lined with 37,000 m^2 (400,000 ft^2) of HDPE material.

The second reservoir holds supernatant water from the tailings area, as well as any other water requiring treatment before it is recycled or discharged to the environment through the monitoring ponds. The capacity of this reservoir is 120,000 m^3; it was lined with 20,800 m^2 (224,000 ft^2) of HDPE liner.

The five monitoring ponds with individual capacities of 5,000 m^3, hold treated supernatant water from the process plant and are used to test treated water before it is

Continued on page 5.

GENERAL LOCATION OF KEY LAKE

Uranium mine lines with HDPE

Continued from page 1

discharged. Unacceptable water is recycled for further treatment. Each monitoring pond was lined with 3,100 m^2 (33,600 sq. ft.) of HDPE.

It was necessary that the liner withstand the severe climate and the icing conditions that would form in the reservoirs and ponds. (The tailings pond was not lined with geomembranes, because the subaerial technique used at Key Lake for depositing results in a laminar structure with vertical segregation of sands and slimes, and thus a very low coefficient of vertical permeability.)

HDPE Specified For Climatic Conditions

KLMC amended its previous specifications to require either 60 or 100 mil HDPE liners. The invitation to tender read: "The HDPE liner shall be capable of withstanding the climatic conditions as outlined.

During regular operation of these facilities, liquid levels will vary continually over a range from full to empty throughout the year.

Parts or all of the liners may be exposed to the full range of climatic conditions for extended periods of time and must be capable of withstanding the effects of sun, wind, rain, hail, snow, etc."

Thus, ice would not only form on the reservoirs and ponds, but it would continually ride up and down the slopes as liquid entered the impoundments and also as treated effluent was discharged.

Ice Loading

Two forces can be exerted by the formation of ice in a lined basin. The first is lateral pressure that is brought to bear on the side slopes of a basin when the entire surface freezes. The second occurs, usually in springtime, when large chunks of ice that break off from the main body are driven by wind and wave action into the side slopes, creating localized point source forces on the liner. Portions of the ice cap may also literally hang on the liner and tear it easily if enough mass has accumulated.

A basin designer can mitigate the destructive potential of ice loading by employing a relatively mild slope, by avoiding materials with a tendency to stick to ice, and by specifying a high strength material in an increased thickness for better puncture and tear resistance.

A mild slope (e.g., the 2.5:1 used at Key Lake) will ease the lateral pressure of a solid ice cap and permit it to ride up the slope rather than impinge on the liner in a direction perpendicular to it. Adherence of ice to a lining material occurs more frequently with roughly textured liners.

Beating the Freeze

The two reservoirs and five ponds had to be relined by September, 1983, before freezing weather conditions set in. On June 27, 1983, KLMC representatives flew to Houston to meet with two

LATERAL ICE PRESSURE ON SIDE SLOPES

ICE CHUNKS RIPPING ON SIDE SLOPES

Texas-based manufacturers of high density polyethylene liners. After an initial consultation, both firms prepared quotations, delivering them the following day, June 28.

Schlegel Lining Technology recommended its 100 mil SCHLEGEL® sheet in order to provide extra security against liner puncture and tear that could result from ice loading conditions. SCHLEGEL sheet has a low coefficient of friction; therefore, it would not have a tendency to stick to ice as might roughly textured liners. Schlegel Lining Technology also offered single-source responsibility to the lining project, from manufacturing the liner through installation and post-inspection. Other lining suppliers who had been considered for the job work only through general contractors or independent installers. It is not uncommon for a lining system to pass through several firms before it reaches the end user.

On June 29, 1983, Schlegel Lining Technology was informed that it had been awarded the contract. KLMC had decided to accept an HDPE liner in a 2.5 mm thickness, rather than the allowable alternate thickness of 1.5 mm, on the basis of data showing that any plastic material's resistance to puncture and tear is a proportional function of its thickness. The incremental cost of the increased thickness was relatively low.

During the month of July, more than 200 rolls of SCHLEGEL sheet were delivered to the Key Lake Mine site. The reservoirs and ponds were constructed in a priority order, determined by the operating needs of the facility. The larger water reservoir was installed first, followed by the second reservoir and then the five monitoring ponds.

Installation of the 73,300 m^2 of liner was accomplished in 36 work days, out of 37 elapsed days, using two shifts of 10-man crews.

Key Lake Mine began full operations in October, 1983.

Potential ice loading problem averted

Schlegel Lining Technology's experience with cold climate liner installation and operation can be seen in the work completed in the summer of 1983 at a new wastewater treatment facility in Caribou, Maine. Caribou is near the northernmost point of the continental United States, where winter temperatures often reach – 30 °F.

Protection of ground and surface waters was a serious consideration in construction planning for the facility owned by the Caribou Utility District. The specifications issued by the joint venture awarded the design-build contract called for lining the three treatment ponds with a high density polyethylene liner.

The ponds are sited 100 feet from the Aroostook River; the substrate on which they were built is coarse, porous gravel. Although the ponds are aerated year-round, they ice over during the winter months.

The mechanical toughness of SCHLEGEL® sheet and its ability to withstand the ice loading conditions prevalent in Caribou during the winter were demonstrated to the customer's satisfaction with case studies of similar installations that are now in operation. Schlegel Lining Technology installed 550,000 square feet of SCHLEGEL sheet at the Caribou project. Post-inspection reports indicate no problems with the lining.

INTRODUCTION

Quivira Mining Company's Ambrosia Lake operations with a design capacity of over 6,000 stpd is the largest uranium mill in the USA. It is served by six underground mines located in the vicinity.

Quivira Mining Company (formerly known as Kerr McGee Nuclear) operated one of the neatest and tidiest mining and milling complexes in the USA until the plant shut down in 1985.

There are several noteworthy water management features at this operation, now operating at a reduced throughput in tune with the market for uranium yellowcake:

1) Macro-recycling of water occurs between Mines-Mill-Tailings-Nearby Mines. Excess water pumped from the mines is discharged to a creek after uranium recovery by CIX and radium precipitation. This water evaporates in part and some returns to an aquifer. Buildup of competing ions due to seepage from the tailings pond results in a deterioration in efficiency of ion exchange recovery uranium from such streams.

2) Excess process water is decanted from the tailings dam and pumped to a series of membrane lined evaporation ponds. Much can be learned with respect to evaporation pond design and lining membrane selection from the early evaporation ponds, and the remedial measures that are employed.

R MINEWATER- PROCESSWATER RESERVOIR
ALSO USED FOR FIRE PROTECTION

35 SETTLING $BaSO_4$ PONDS

3) CIX performance has dropped off in comparison with original design parameters probably because of a general increase in dissolved salts - competing ions and fouling species - in the water. In order to maintain a 1 ppm U maximum discharge to the creek, the resin must be eluted up to 100 times per month compared with the initial design of 16 times per month when TDS (e.g., Cl^-) was lower in the solution.

4) Quivira Mining Company employs in situ leach of worked out stopes on a small scale. The water recovered from the mines is processed by ion exchange to recover uranium which accounts for about 5% of the present reduced U_3O_8 production rate of the operation of about 2.0 mm lbs per year. At mines 5 and 36 which are the furthest from the mill, treated water is discharged for use in irrigation by local ranchers after uranium recovery and Ra precipitation.

5) Water treatment practised at Quivira's Ambrosia Lake operations include:

° Boiler Water Treatment	Anthracite Filtration IX Cation Softening Anti-Scalant Addition (phosphonate) De-Aeration O_2-Scavenging
° Acid Cooling Coil Waters	Anti Scaling Chemicals added
° Domestic Water Treatment (for showers and toilets)	Sand Filtration chlorination
° Potable Water	Treatment of "domestic water" by charcoal filtration Reverse Osmosis
° Uranium Recovery from Minewater	Continuous Ion Exchange and Elution
° Radium Removal from Minewater for discharge	$BaCl_2$ addition
° Sewage	?

6) Quivira Mining Company does not have a problem in water conservation or supply. There is a relatively high cost of disposing of contaminated tailings decant water.

7) Water balance at the mill is regulated on a chloride level in mill water - i.e., chloride balance is the critical issue.

8) The tailings impoundment is unlined and is located on an alluvial plain - it is therefore porous and loses water through seepage. A seepage collection trench is currently under construction at the toe of the dam at a cost of around $500,000.

9) Tailings are not neutralized before being pumped to the pond. During seepage through the alluvia pH increases.

10) A major source of Cl^- to the system is from the stripping of the loaded SX organics using 0.6 Molar NaCl. This adds Cl^- to the raffinate and through discard of yellowcake filtrate to tailings at 0.3M concentration.

11) Biological processes observed in the minewater ponds before discharge appear to remove some uranium, selenium and molybdenum from solution.

12) As excess process water excess is evaporated the rate of evaporation from the ponds decreases as the salt concentration increases in the pond. Frest water evaporates at 48" per year, yet the salt laden solution in the pond evaporates at only 40" per year. There is a distinct odor downwind from the evaporation ponds.

KERR-McGEE NUCLEAR CORPORATION
URANIUM PROCESSING FLOWSHEET

LOCATION 25 miles north of Grants, New Mexico

OPERATION STARTUP 1958

CLIMATE:

Arid continental climate. Rainfall 9 - 10 inches per year. Evaporation 48"/yr for water.

MILL THROUGHPUT	Design Capacity	6200 stpd
	Present Operating Rate	2500 stpd for a 4 day week

URANIUM GRADE 0.18% U_3O_8 3.6 lbs U_3O_8 per short ton ore

WATER SOURCE Underground Mine dewatering

NET WATER CONSUMPTION
(based on flow rate)

At full production	1500 USgpm for 6200 stpd ore
i.e., 10,800 s tons water per day	= 1.74 tons water/ton ore treated
At reduced production	500 USgpm for 2500 tpd (4d/week)
3600 s tons water per day yearround	= 6300 s tons per operating day
	= 2.52 s tons water per one ore

NET WATER CONSUMPTION
(based on Metallurgical Balance)

1.3 - 1.5 t new water consumed per ton ore

SOLUTION REQUIRED PER TON ORE

1.7 - 2.0 tons water/ton ore milled
includes 0.45 tons recycled process water to mill

The sandstone ore is mined at depths of 600 to 1400 ft. Each mine generates 200 to 2000 USgpm water. Ore is hauled to the mill by truck. Ore stockpiles at the mines are not lined.

METALLURGICAL PROCESS

Ore is crushed in two stages to minus 1" then sampled prior to milling in open circuit rod mills. It is ground to minus 28 mesh and leached at 70% solids in sulfuric acid using

sodium chlorate as oxidant. Leaching takes 3 - 4 hours and is accelerated by steam heat. Heat is provided by wasteheat recovery from the acid plant supplemented by boilers. Cooling water from the acid cooling coils is added to the rodmills at 80-90°F. Sand and slime are separated by cyclones. Sand is washed in acid solution in five stage rake classifiers prior to being disposed of to the tailings pond.

Slime is washed in 7 stage CCD circuits of which the final stages are Enviroclear high rate thickeners.

Solution is filtered and clarified and fed to an SX circuit where uranium is extracted by a tertiary amine in an organic kerosene phase containing isodecanol. Organic advances at one third the rate of aqueous solution advance through the SX plant to achieve a 3-fold concentration.

Raffinate is returned to the CCD and rake classifier circuits as wash solution with 20% bleed to tailings.

Uranium is concentrated a further ten times in a 4 stage stripping circuit using a sodium chloride solution. Uranium is preipitated using anhydrous ammonia, air and steam, thickened and settled, then dewatered and washed in three stages of drum filtration. The yellowcake filtrate is pumped to the tailings pond. Yellowcake is dried and drummed, or more lately shipped in slurry form to the refinery.

RECOVERY

Overall uranium recovery is 90-97%. Soluble loss of uranium in the CCD circuit at the current reduced throughput is 0.25%.

OPERATING COSTS

Mining accounts for two thirds the total operating costs. Sulfuric acid is the biggest single expense.

ACID CONSUMPTION

130 lbs concentrated H_2SO_4 is required to process each short ton of ore. Sulfuric acid is produced on site by burning sulfur.

NACL CONSUMPTION

6 - 7 lbs NaCl per ton ore treated. Additional chloride is added to the system as chlorate used as the oxidant.

SCHEMATIC DIAGRAM
OF A MINE

4

U_3O_8 RECOVERY SELECTION

Leach Liquor

The Ambrosia Lake ores contain several elements that also dissolve in sulfuric acid e.g., iron, selenium, vanadium, molybdenum.

The ore grade at 3.6 lbs/ton ore is high grade and the CCD wash solution has a relatively high tenor.

SX is economical to use at this concentration and favored over IX because it is more selective for uranium recovery from the leach liquor.

Minewater

Concentration of competing ions in the minewater especially at the time the IX plants were designed, was very much lower than in the leach liquor.

SX is not economical for treatment of very dilute solutions because organics entrainment losses are a function of flow rate rather than uranium tenor. Consequently the solvent losses for very dilute solutions are expensive in relation to the uranium values recovered - also the SX loadings from such low tenor solutions is low.

Consequently ion exchange is preferred for U_3O_8 recovery from mine solutions of the tenor encountered i.e., 5 - 12 ppm U_3O_8.

Because of the higher concentrations of competing ions in minewater feed to the IX plant, ideally a multi stage CIX plant would be required. However, given the mere 100,000 lbs per year U_3O_8 recovery by IX at a market value of $2 million/year it is difficult to justify a suitable multi stage CIX system such as NIMCIX requiring an investment of about $1.5 million, when the existing less efficient 2 stage IX systems do work after a fashion - albeit requiring many more costly elutions and undoubtably greater annual resin consumption costs.

Minewater from section 17 is generally lower in chloride than the rest and is used as boiler water after demineralization and addition of anti scaling agents.

Investigations carried out in 1979-81 were described showing how a variety of biological processes take place in the Quivira Mine effluent ponds which remove some of the residual pollutants including metals and sulphates, with algae acting as biofilters to remove suspended solids and removing soluble metals by adsorption.

Although not deliberately employed for this purpose, these processes have been described

by BRIERLEY, et al. (1980) and BRIERLEY AND BRIERLEY (1981) available from Randol International Ltd. on request.

1) <u>Water to Tails</u>

2500 tpd solids to tails @ 40% solids = 3750 stpd Water 4 d/week

= 297.6 USgpm Water to tails

2) <u>Water Recycled from Tails</u>

2500 tpd 0.45 tons water/ton ore X 4days/7dweek = 89 USgpm ave.

Dearborn supplies anti-scaling reagents for the acid cooling coil circuit and the boilder feed water.

ION EXCHANGE U_3O_8 RECOVERY - MINEWATER

Quivira Mining Corp. recovers uranium from minewater before it is released to the creek. After ion exchange uranium recovery, radium is precipitated by $BaCl_2$ addition at the discharge from the IX plant and settled.

The IX plant was installed in 1963. There are now 5 IX circuits at the mill plant each with two stages of upflow adsorption in contactors designed by Kerr McGee Corp.

At Mines 35 and 36, there are a further three CIX circuits.

A multistage continuous CIX contactor was purchased from Solution Engineering, Denver, but was later abandoned in favor of the simpler K-M 2 stage system. The price of this installation was reported in 1980 to be $500,000 compared to $1.25 million for a comparable NIMCIX unit.

In the late 1950s when the operation started there was virtually no uranium in the minewater. Uranium levels gradually increased over the years until a point was reached when the ion exchange recovery yielded the present level of about 10-12,000 lbs U_3O_8 per year.

Details of the ion exchange recovery system and performance were obtained from the SLOAN & MA (1976) and RANDOL (1980).

Since the original description of the KERMAC ion exchange recovery of uranium several changes have been noted:

1) Quality of minewater delivered to the Mill CIX unit has changed and now contains 28000 ppm TDS including 1600 ppm $SO_4^=$ and 150 ppm Cl^-.

   Under these conditions the U_3O_8 (still 10-12 ppm in the feed solution) loads to only 0.6 lb.ft³ (10g/l) before breakthrough occurs.

2) Minewater from Sections 35 and 36 runs 1300 ppm TDS, 1600 ppm $SO_4^=$ less than 10 ppm Cl^- and loads resin to 2 lbs U_3O_8/ft^3.

3) Resin fouling, believed to be SiO_2 and $CO_3^=$, is overcome by acid washing in pH1 HCl every few months using recirculating solution to clean the resin.

4) Original design called for 16 resin elutions per month. Currently it is necessary to elute 100 batches of resin per month. This reduces the economics of the operation.

5) Resin from Section 34 and 35 Mine IX plants are transported to the central mill for elution. Transfer of resin so often is labor intensive and expensive. Quivira is anticipating changing to an elution of resin inside the adsorption vessels and it is expected that the epoxy coated carbon steel vessels will corrode.

6) Because of the reduced loading achieved in the IX plant, the resin inventory has had to be increased to keep U_3O_8 in the minewater effluent within permit limits of below 2 ppm U_3O_8. This in turn has required a much greater load on the resin elution circuit with correspondingly greater cost of reagents.

7) Eluate is now mixed with the SX strip solution for direct precipitation of yellowcake.

KERMAC CIX

The Kermac System is described in the Randol Report on Continuous Ion Exchange/Resin in Pulp and by SLOAN & MA (1976). Very similar contactors are used at the The Uranium Resources Corporation, Benavides in situ leach plant in Texas.

Uranium is loaded on resin in two upflow fluidized beds in series. Feed solution flows down a central feed pipe to a conical section at the bottom of the contactor, then up through a perforated plate through the expanded bed of resin occupying the greatest part of the vessel. Solution then overflows across a launder and flows by gravity to the second column identical to the first.

When breakthrough is observed in the barrens from the tail column, the resin contents of the lead column are transferred to the elution vessel. Partly loaded resin from the tail column is transferred to the lead column and loading recommenced. Resin is transferred using hydraulic venturi eductors.

Resin is eluted in a downflow packed bed chamber using a split elution sequence to achieve higher eluate concentration.

This two stage system works well for very dilute feed solutions such as minewater as long as equilibrium is not depressed by competing ions.

This system is very similar to the so-called UTAH-type contactors used by several South Texas in situ leach operations. The name UTAH-type is derived from the first application of this type of contactor at the Utah Copper Company where they were designed by R. Porter.

CONSTRUCTION OF COLUMNS

8' x 8' with cone at bottom. There are no baffles in the tanks. At the bottom of each tank is a perforated disc with 1/8 inch holes on 3/4 inch centers.

Originally there were twice this number of holes in the solution distributor disc, but it was found to work better if half of them were plugged.

MATERIALS OF CONSTRUCTION

Mild steel loading columns without any coating.

Elution columns are of mild steel lined with a special epoxy designed to resist the high chloride content. The epoxy coating has lasted since the original application in 1962.

RESIN TRANSFERS

Resin is transferred from the loading columns to elution tank by means of water jet eductors at the bottom of each column which enter each tank below the perforated plates. Resin is transferred four times in each cycle. A single 5HP high speed water pump powers all eductors for resin transfers from one tank to another and in/out of the elution vessel.

ELUTION CYCLE

As uranium levels in the CIX barrens start to rise in the tail of the two loading columns, the lead column is taken off line and resin transferred to the elution tank for elution.

The present elution system consists of two tanks (350 and 125 U.S. gal.) in series.

A split elution process is employed whereby the second elute from the previous day is used as a primary eluant to yield a rich eluate. This rich eluate runs about 10 g U_3O_8/l which is a very good tenor indeed. Then the partly eluted resin is eluted further using wash solution from the previous day.

The 3 stage split elution requires 6 hours downflow elution with 1.8 molar NaCl at pH 8.0-8.2.

During the cycle, resin moves as follows:

1. Eluted resin is held in storage in a tank.

2. When required eluted resin is transferred into the #2 loading tank (tail tank) where it is loaded for several days.

3. Once barrens from the tail tank rise indicating breakthrough, resin from the lead tank #1 is transferred to elution, and resin from the tail tank is transferred to the lead tank #1.

4. When the new resin batch in tank #2 loads to a point that barrens approach 1PPM U_3O_8, the resin in the lead tank is transferred to the elution tank.

5. After elution, the resin is rinsed and transferred back to the eluted resin storage tank or direct to the tail tank #2 as required.

ADVANTAGES OF KERMAC SYSTEM

1) Very simple to design and operate

2) Works very well for low concentrations of Uranium to be recovered in the presence of low competing ion concentrations.

Loading Kurmac CIX column in a two-column cascade

DISADVANTAGES OF KERMAC SYSTEM

1) High competing ion solutions would require numerous Kermac contactors in series at which point capital cost and resin inventory would go up to make this system uncompetitive with multiple stage column contactors.

2) In multiple stage configuration the Kermac contactor would resemble a Porter CIX system only it would not run truly continuously as the forward flow through each contactor is halted during resin transfer.

3) Scaleup of contactor diameter is limited. Distribution of feed solution across the contactor is achieved using a perforated plate. This works well only up to a certain tank diameter beyond which channeling can be expected to occur on account of the feed having to be distributed from the central pipe.

   For large flowrates several lines of contactors are required.

   Further contactor scaleup would require installation of more sophisticated feed distributors such as the patented Proter system.

RADIUM REMOVAL

Radium must be precipitated from minewater to meet the 3 piC/l radon effluent limit imposed by the state.

$BaCl_2$ in a saturated solution is mixed via a chemical feed pump to the ion exchange plant effluent.

0.023 lbs. $BaCl_2$ per ton water is consumed in this way. Barium Chloride costs $450/st i.e., based on an effluent flow of 4000 gpm, $BaCl_2$ is calculated at 662 lbs/day at a cost of $149/day.

After $BaCl_2$ addition the water is settled in two unlined ponds in series before the water is discharged in one case to a "creek" and in the second case to a ditch from which the ranchers draw irrigation water.

IMPACT OF MINEWATER DISCHARGE TO ENVIRONMENT

Impact of uranium minewater seepage on groundwater at Ambrosia Lake is similar to that at other Quivira Mining Company operations such as at Churchrock No. 1 Mine, with the

exception that at Ambrosia Lake, uranium is recovered by IX, but not at Churchrock No. 1.

TAILINGS DAM

Tailings at pH 1.2 and 40% solids or less are pumped to the tailings pond and discharged via perimeter spigots. The tailings are coarse. Ore grind is to Minus 28 mesh, 33% minus 150 mesh and 20% minus 200 mesh.

The original tailings dam was designed and built by Stearns Rogers in 1958 long before there were any environmental concerns about tailings disposal.

Every four months a state approved engineer must submit a report on the tailings pond to demonstrate that it conforms to the Bureau of Mines stability test.

Tailings are discharged to make a very wide peripheral beach with a small pond. No underdrains are installed to drop the phreatic level at the wall as such design features had not been considered when the dam was built.

At the date of the latest Randol visit the dam was reaching an estimated height of 100-150 ft. A new seepage collection trench is being excavated at a cost of $500,000 and it was clear that a significant volume of seepage solutions were collecting in the trench.

The site was visited just after a heavy rainfall and erosion features were noted on the outer surface of the dam wall. These were being filled in. Ever since the failure of the Churchrock tailings dam of an operation belonging to another company, uranium tailings dam construction has been very strictly monitored by the state.

SEEPAGE FROM TAILINGS

50 - 70 monitor wells are scattered around the Quivira Mining Company site, many of them around the tailings dam. Collecting samples of water from these wells is the fulltime task of Felix Vigil. Monitor wells go down to the contact at the bottom of the alluvia with bedrock - normally a shale at a depth of 10 - 50 feet below the surface.

Monitor well samples indicate that a plume of seepage from the tailings dam extends about half a mile east of the dam.

Seepage water quality indicates that there is some improvement in quality of tailings solution as it migrates through the alluvia as has been observed at several other uranium tailings sites.

High chloride levels in minewater from the vicinity of the tailings pond indicate that seepage losses do occur. Leakage into the mines may occur due to horizontal migration of solution until intercepted by vertical leakage points such as sample drillholes, ventilation shafts, etc. Minewater as high as 200 ppm Cl^- has been encountered as evidence of such seepage.

Also, when a lined evaporation pond was constructed close to the toe of the dam, large gas bubbles accumulated beneath the lining even as it was being laid down which were assumed to be carbon dioxide from a reaction between acid seepage from the tailings pond and carbonates in the soil.

It is almost certain that in 1984 a new uranium mill would not be allowed to discharge tailings to an unlined pond in an alluvial plain except under the most convincing circumstances where it could be shown that local factors would remove undesirable species from the solutions or that they would be contained in an aquifer that already was so poor in quality as to render the natural waters totally unusable before the impact of tailings seepage.

In this case mill tailings seepage and leakage into nearby mines has resulted in a gradually increased cost and deterioration in efficiency of the ion exchange minewater treatment process.

ENVIRONMENTAL PROTECTION AUTHORITY

New Mexico is an "agreement state" and as such falls under the state regulators as far as environmental protection is concerned. This means that the operation must comply with state regulations which are supposed to be at least as strict as those of the Federal Nuclear Regulatory Agency.

Water discharged to navigable streams must comply with the NPDES permits - National Pollution Discharge Elimination Service. These require maximum 2ppm U/l and 3piC/l Radium in discharged effluents. It is questionable whether such regulations apply in this case since the watercourse into which the treated minewater is being discharged is normally dry and is certainly not a navigable waterway.

Limits on discharged water	U	1 ppm max
	Ra	3 piC/l max
	pH	6 - 9

Remainder of environmental regulation is by the New Mexico Department of Environmental Improvement soon to become a cabinet position removing it from the Department of Health.

EVAPORATION PONDS

Once water has been involved in uranium mineral processing it may not be discharged except to a lined evaporation pond.

Initial evaporation ponds were not lined until the law was changed. Since then the first two sets of a total of 5 lined ponds have been abandoned. As water is recycled, so dissolved solids and chloride build up and must be bled.

EVAPORATION POND NO. 8 & 10

The first attempt to line a pond was pond 8 at the toe of the tailings pond. It was planned to line the pond with PVC on the floor and chlorinated polyethelene on the sides. In doing so a problem arose in that gas bubbles developed under the membrane and lifted it in such a way that they could not be removed. The gas generation was ascribed to a reaction between acid seepage from the dam and carbonates in the alluvia beneath the pond. A similar effect would be observed if acid effluent were initially discharged to the pond before it was lined.

Several "burpvalves" supplied by Watersaver Company were tested without success as a means of getting rid of the gas.

Soil covers were applied to try and weigh the lining membrane down.

Eventually pond 8 was abandoned. PVC floor lining where covered by sediment appears still to be in good shape. When exposed to the New Mexico sun and heat, however, plasticiser evaporates and the membrane soon decrepitates.

From this experience it can be demonstrated that evaporation ponds adjacent to seeping acid tailings dams may be impossible to line satisfactorily if located over carbonate containing strata. "Burp valves" do not work as a means of releasing such gases.

Pond 10 was designed and installed by Jacobs Engineering in 1976.

EVAPORATION PONDS 11 - 15

Ponds 11 - 15 were installed with PVC floors and 20 mil CPE sloping sides in 1977-8. The ponds were designed and installed by Jacobs Engineering and the membranes supplied by Panasall.

The membrane panels are installed with the long side seams parallel with the wall of the

pond. Sides are sloped at a gradient of 2.5:1 against sandy material making up the ponds walls. The ponds are quite large - the five ponds totalling 110 acres were installed for $2 million in 1978.

Several problems have been experienced:

- The steep sides are vulnerable to wave action - slope stability of the earth walls was inadequate and the soil beneath the membrane sloughed inward putting the membrane liner sides under tension.

- The membrane panels were factory seamed parallel to the wall of the dam. These seams have failed in places due to tension.

- Rodents found their way to the membrane from below and gnawed holes through the plastic. The holes allow water to the underside of the membrane allowing the earthen wall of the pond to become wet and plastic.

Ralph Yetter, plant engineer for Quivira Mining Company has been responsible for maintainence and repair of the pond linings and concludes after observing these ponds since they were installed that failure is due mainly to the steep 2.5:1 sides of the ponds.

I-83

Wave action combined with slope instability has been the main cause of lining failure. The failures were exagerated by improper panel orientation, rodent holes, membrane embrittlement and seam failure on the 20 mil CPE membranes on the sides. The basic design of the pond appears to be failure prone regardless of membrane selection as discussed below.

PONDS 16 - 21

Ponds 16 - 21 were designed and installed by Kerr McGee Corp. along the lines of the Jacobs Engineering design of ponds 11 - 15. These ponds covering 160 acres were installed in 1979-80 at a cost of $3.2 million. In these ponds the floor is again PVC with hypalon sides. The basic wall configuration of the ponds is similar to that of the earlier ponds installed by Jacobs Engineering with a 2.5:1 vertical slope.

Once again wave action against unstable slopes of the earthen pond walls has caused the wall material to slump behind the hypalon lining membrane. This has caused tension in the membrane and resulted in failure.

EXISTING DESIGN

HINDSIGHT RECOMMENDATION

In ponds 16 - 21 the membrane panels are oriented parallel with the walls making them apparently more susceptible to seam failure than if the panels were oriented across the slope.

Again rodents have gnawed holes in the membranes on the exposed sides which allowed moisture to get behind it and to fluidize the earthen wall material in conjunction with wave action. The diagram illustrating how this caused failures on side slopes of dams 11 - 14 applies equally well in this case.

After the nylon reinforced hypalon membranes were installed at Quivira Mining Company's ponds, there has been some discussion as to the reason for delaminations in some installations. One possible contributory factor noted by Ralph Yetter is that the individual strands of nylon reinforcement are too close together.

One observation made (No qualitative test data available) is that when reinforcing fiber with a scrim that is too tight is used, then the bonding area in the spaces between fibers is too small for a good bond between the two layers of membrane.

The observation seems plausible and is an aspect of thermobonded reinforced membranes which is worth being aware of and further investigation.

MEMBRANE REPAIR

Where membranes on the walls of the evaporation ponds are damaged, this usually occurs in the form of failure along seams where the supporting wall embankment has slumped and put stress on the membrane.

The cost of changing the slope profile of the walls of the impoundments would be exorbitant. To date the repairs that have been made involve replacement of parts of the membrane panels. Several alternatives have been tested:

1) Chevron Industrial Membrane CIM painted over fiberglass reinforcement to make a new membrane to span holes and rips in the hypalon liner on the side of pond No. 16.

   Five gallons of CIM were required to cover an area about 15' long X 2' wide at a cost of $15/gallon plus fiberglass. The roller application of the liquid membrane was found to be messy and time consuming although Quivira Mining described CIM as a "very good product."

2) Hypalon patches on hypalon. These proved difficult to glue.

3) CPE patches adhered to hypalon using Staff Industries CC801 adhesive works very well. Expansion flaps are left in the inserted CPE panels. Liberal amounts of adhesive are applied to both membrane surfaces before pressing the two together. The glue works best in warm weather. It was supplied by:

   Staff Industries Inc.
   240 Chene Street
   Detroit, MI 48201

SUGGESTED ALTERNATIVE EVAPORATION POND DESIGN

Since wave action appears to try to turn a steep wall into a low angle beach, Quivira Mining believes that the beaches of the evaporation pond should be constructed that way to start with.

At Quivira Mining Company it has been observed that where the water level is dropped so that the waves run up a shallow beach, then there are no slopes to become unstable. The shallow beach areas become protected by a layer of silt. In order to get the volume required in the ponds it is necessary to have an adequate depth. To achieve this an inverted "tophat" profile design has been suggested. Such a design would require more real estate but hopefully would avoid the expensive maintenance and potential for leaks.

INTRODUCTION

The following draft paper was located in RANDOL files and unfortunately does not indicate the author's name. Nonetheless this paper is of interest for the following reasons.

1. A systems approach is described - In this case after Rabbit Lake ore was depleted, ore from nearby Collins Bay "B" Zone is sufficiently different to require a change in metallurgical process. Increased levels of environmentally sensitive metals in the effluent from the treatment of new ore lead to a change in metallurgical process, and inclusion of new purification and effluent treatment processes.

2. Useful methods for removal of zirconium and arsenic etc. from effluents are described.

   - Precipitation of zirconium as a phosphate by addition of phosphoric acid, and filtration.

   - Precipitation of arsenic as ferric arsenate at pH 3.8 while is pH is adjusted by MgO addition to yield an iron cake.

   - SO_2 to convert Fe^{++} to Fe^{+++} for ferric arsenate precipitation.

   - High pH nickel precipitation to pH 12.5-12.7 with lime to precipitate nickel.

   - Radium removal by addition of $BaCl_2$.

   - Avoiding ammonia releases in effluents by selecting an alternative means of stripping loaded SX adsorbent and for pH adjustment.

Abstract

Gulf Minerals (Canada) Limited's Rabbit Lake Uranium Operation is located in the northern portion of Saskatchewan, 198 miles southeast of Uranium City and 134 miles northwest of Lynn Lake, Manitoba.

This paper describes flow sheet changes to solve operating problems and briefly describes future changes to accomodate the new "B" Zone ore.

The Rabbit Lake mill was designed to process 1600 dry tons per day of uranium ore, with an average grade of 0.370 percent U_3O_8. In 1981, the mill processed 2040 tons per day at a grade of 0.231 percent U_3O_8.

The process modifications and flow sheet changes that allowed this increase in tonnage will be discussed in relative chronological order.

Mill feed was introduced on June 10, 1975, the original equipment consisted of an Ingersoll Rand hydraulic breaker mounted over a 24" square grizzly. The - 24" ore was fed to a 20" X 6" semi autogenous grate discharge mill close circuited with 20" cyclones, the mill discharge was screened on a tyler double deck screen with the undersize (8 mesh) reporting to the cyclones, the screen oversize was returned by conveyor belt to the mill feed chute.

The cyclone overflow (28 mesh) was thickened in a 100' diameter thickener to obtain 55 percent solids for the leach circuit.

The leach circuit consisted of two slurry holding tanks and five leach tanks.

The leach discharge was washed in five 100' diameter thickeners to remove the soluble uranium.

The pregnant liquor was clarified in a 60' diameter clarifier and pumped to three 7' diameter sand filters.

The clarified pregnant aqueous was pumped to a solvent extraction circuit for concentration and removal of impurities, after the stripping phase the uranium was precipitated from the pregnant strip liquor by adding ammonia in two precipitation tanks.

The precipitated yellowcake slurry was thickened and washed in two counter-current thickeners, centrifuged and dried in a multi-hearth dryer.

The dried product was passed through a hammer mill before being packaged in 45 gallon steel drums.

The slurry from the last C.C.D. thickener was pumped to three neutralization tanks where milk of lime was added before discharging to the tailings pond.

As with most mill start ups, problems were encountered shortly after feed was introduced. In 1975, tonnage was limited due to several reasons. Wear on the S.A.G. mill liners was excessive due to uneven feed rates to the mill allowing the mill to run empty, at this time the mill was charged with 4" balls, these were removed and replaced with a charge of 1 1/2 and 2" balls.

The acid section of the mill, was lined with urethane rubber. These liners failed in 1975, shortly after start-up, all C.C.D. thickeners, associated tanks, solvent extraction cells, yellowcake area tanks and tailings line were affected.

The decision was made to replace all lining with fiberglass and to replace the tailings line with sclairpipe. This project would proceed into 1976 and proved to be an exercise in ingenuity as thickeners and tanks were bypassed to allow full mill operation during the relining process.

In 1975, the C.C.D. thickener diaphragm pumps were found to be an impractical design, necessitating major modifications.

In 1976, the mill tonnage reached 63.5 tons/hr.

The hydraulic rock breaker was abondoned as it was impossible to operate during the winter months. A used Kue Ken double toggle 42" X 48" crusher was purchased and temporarily installed during construction of a permanent crusher facility.

A new off gas scrubber was required for the yellowcake dryer and was purchased in 1976.

Considerable improvements to the mill ventilation system were required to control radon gas, venturi scrubbers were installed on the leach tanks, ventilation was steadily improved over the next three years.

In 1977, the tonnage increased dramatically to 80.5 T.P.M. due mainly to the completion of the crusher installation.

Major modifications were carried out in the grinding circuit.

The neutral thickener was removed from service when it was discovered that cyclone overflow could be maintained at 55 percent solids with no adverse effection on the grind.

A used 9'6" X 17' Nordberg ball mill was purchased and installed as a regrind mill. The Tyler screen and associated recycle belts were removed.

The S.A.G. mill discharges directly to the regrind which is close circuited with the 20" cyclones.

Mine drainage water was pumped to the mill for treatment and disposal to tails. A decant barge was installed at the tailings pond and a second precipitation pond was added.

Flocculant and Barium Chloride mixing stations were installed at the tailings area.

Pump capacities were increased in the solvent extraction area.

In 1978, tonnage increased to 86.8 tons/hr. the neutral thickener was converted to a sixth C.C.D. thickener.

In 1979, tonnage again increased to 105.9 tons/hr.

Two more leach tanks were installed and the acid plant capicity was increased to 200 T.P.D. from 150 T.P.D.

A test sandfilter was installed at the precipitation pond effluent discharge.

In 1980, tonnage was 117 tons/hr.

Four inch balls were added to the S.A.G. mill with a control system to prevent the mill running empty.

A mass flow system was insatlled from #1 slurry tank to the leach circuit to provide even feed.

A clutch was installed on the regrind mill drive, originally the synchronous motor was sufficient to start the mill when installed on a power grid in the south, but at Rabbit Lake the power factor could not be maintained to start the mill when it was heavily loaded.

A grate discharge was installed on the regrind and a trommel on the auto mill, the trommel undersize feeds the cyclone feed pump box.

A fourth sand filter was installed in the clarification circuit.

The lime screws feeding the lime mill were increased in size in order to neutralize the increased tonnage of tailings.

The Ingersol Rand Hobgoblin was recommissioned as an oversize rock breaker in the crusher building.

Extensive remodelling of floors and sump areas was carried out in 1980.

In 1981, tonnage was 124 tons/hr.

The diaphragm pumps in C.C.D. were recommissioned using a hydraulic drive system.

The grate discharge opening on the S.A.G. mill was increased allowing fully autogenous grinding.

<u>Slide</u> - Flow Sheet of Existing process.

The end of the Rabbit Lake orebody is in sight. Mining operations in the Rabbit Lake pit will cease in 1983. Enough ore will remain in stockpile to provide feed to the mill until 1985. The remaining years will see a marked reduction in the production of yellowcake as ore grades drop.

In order to insure continuity of operation, Gulf Minerals Canada Limited is presently attemting to obtain regulatory approval to develop a nearby orebody named the Collins Bay B-Zone, to provide ore for processing the existing mill.

If the planned mine development schedule becomes a reality, the first ore from the Collins Bay B-Zone deposit will be delivered to the mill in 1985.

The orebody contains approximately 3.5 million tons of ore grading 0.453 percent U_3O_8. The total reserve contains 31.3 million pounds of U_3O_8.

The Rabbit Lake and Collins Bay B-Zone orebodies have major mineralogical differences. A comparison of the analysis of typical samples of ore from Rabbit Lake and the Collins Bay B-Zone is given in Overhead 1.

Typical Rabbit Lake Ore Sample Analysis

		Rabbit Lake Sample (%)
U_3O_8		0.31
Arsenic		0.003
Nickel		0.014
Molybedenum	Approximately	0.002
Iron		-----
Vanadium		0.021
Thorium dioxide		-----
Sulphur		-----
Phosphate		0.16
Carbonate expressed as Carbon dioxide	Typically	2.0 - 3.0 %

Typical Collins Bay B-Zone Ore Samples Analysis

	H.R.I. Average Grade Uranium Sample (%)	L.R.C. High Grade Uranium Composite Sample (%)	L.R.C. Low Grade Uranium Composite Sample (%)
U_3O_8	0.62	15.0	0.28
Arsenic	0.47	10.2	0.49
Nickel	0.35	8.27	0.36
Molybdenum	0.01	0.12	0.015
Iron	3.11	1.94	1.20
Vanadium	0.021	0.12	0.047
Thorium dioxide	----	0.040	0.003
Sulphur	0.07	0.56	0.10
Phosphate	0.02	----	----
[illegible]nate expressed as [illegible]bon dioxide	0.20	0.29	0.04

Metallurgically, the greatest difference is a higher concentration of nickel, molybdenum, zirconium and arsenic bearing minerals in the latter.

Nickel and arsenic are presently generally in combination as niccolite, a nickel arsenide mineral which is often found massive, in combination with pitchblende. Some minor sulphides have also been recognized including millerite (nickel sulphide), galena (lead sulphide), chalcopyrite (copper iron sulphide), pyrite (iron sulphide) and ankerite (a dolomitic limestone, containing iron), although the sulphur content is low.

Gangue materials include serecite and kaolinite rich graphic clays, chlorite, and carbonaceous material, generally in a host sandstone.

Uranium is present as uraninite, pitchblende and coffinite, the former often found massive or in fracture fillings, usually in association with niccolite.

From these and other analysis, there is an apparent, though not absolute, relationship between uranium, nickel, and arsenic concentrations in the orebody.

In designing modifications to the mill so that it can accept the Collins Bay B-Zone ore, there are a number of environmental constraints, which affect the selection of the specific processes to be used.

The present Rabbit Lake mill consumes approximately 0.70 pounds of anhydrous ammonia for every pound of U_3O_8 produced. While some of the ammonia added is removed in the tailing neutralization and precipitation processes, a significant percentage reports with the effluent at the final point of discharge. Regulatory authorities have directed this company to reduce ammonia levels in the effluent to a target level of 15 mg/l. This represents a reduction, of present levels, of the order of 95 to 97 percent. In addition, the significant quantities of arsenic and nickel in the Collins Bay B-Zone ore require special consideration, to ensure that their concentrations in the final effluent were less than 0.5 mg/l in each case.

Process Selection Description

Introduction

Early leaching tests confirmed that both arsenic and nickel would solubilize under leaching conditions which are favourable for uranium, and that extraction of both of these elements would be in excess of 80 percent. A series of physical tests was therefore conducted, to determine wheather the minerals of nickel or arsenic could be effectively separated from the uranium minerals, before the leaching stage of the process. Gravity separation and flotation were both evaluted, but no reasonable degree of separation of arsenic and nickel from uranium was achieved. These techniques were therefore abandoned in favor of chemical removal

of dissolved nickel and arsenic, from effluent solutions, prior to discharge.

The process, as it is conceived today, is as shown on Slide of Flow Sheet.

Test work confirmed that, with minor modifications, the crushing, grinding, leaching and countercurrent decantation processes, in existence, were suitable for beneficiation of the Collins Bay B-Zone ore. Major modifications will, however, be required to the solvent extraction process, to the precipitation process, and to the tailing disposal and effluent treatment processes.

The existing grinding circuit is satisfactory for Collins Bay B-Zone ore. No changes are required to the equipment or equipment layout. The ore is basically a sandstone which is readily amenable to grinding. It is significantly easier to grind than the existing Rabbit Lake ore, having a Bond work index of 10.3 to 10.7, as compared to 14 to 16 for the Rabbit Lake ore.

During actual grinding operations, some adjustments of the circuit operating parameters may be expected, to ensure production of a suitable grind.

Test work has indicated that satisfactory extraction of uranium can be realized with the available retention time of 7.5 to 10.5 hours. Sulphuric acid consumtion will be approximately 100 pounds per ton, which is 50 to 60 percent of the Rabbit Lake consumption. The major change in leaching conditions is the significant increase in sodium chlorate consumption which will be approximately 16.5 pounds per ton, or 300 percent of the present consumption. The projected average leaching conditions will therefore be:

- Grind	Nominal minus 35 mesh.
- Feed slurry density	50% solids by weight.
- Retention time	Six hours minimum
- Leach temperature	50 to 55° C.
- Free acid	15 to 30 g/l.
- Terminal emf	Minus 400 to 450 millivolts.

The countercurrent decantation and clasification ciruits will remain essentially unchanged. Although process economics may justify an additional seventh stage of C.C.D. thickening, that addition is not an essential modification to enhance the existing circuit's capability for processing the Collins Bay B-Zone ore.

Initial test work, with leach liquors from the Collins Bay B-Zone ore, was directed towards the application of the existing solvent extraction circuit, with ammonium sulphate stripping, to the purification and concentration of those liquors. Two major disadvantages were identified:

- Rates of sludge formation at the interface between the organic and aqueous phases in the stipping circuit, were several orders of magnitude higher than presently experienced.

- To continue to use an amonium sulphate strip would involve the design onstruction of a process for removing ammonia from the effluent, to achieve the objective of 15 mg/l of ammonia in the effluent.

Sludge formation rates would be effectively reduced by various techniques, which involved pretreatment of the solvent extraction feed solution, but not eliminated entirely. In addition, although a process for removing ammonia from the effluent does exist, its ability to extract at the required efficiency is questionable. As a result, the existing tertiary amine, amonium sulphate solvent extraction process was abandoned.

Test work was then directed at a solvent extraction circuit which would use existing equipment and could be operated with an alternative stripping reagent. Sodium chloride and sodium carbonate were both evaluated and sodium chloride, in particular, was found to be ideal.

Although sodium chloride stripped the uranium efficiently from the loaded organic solvent, with a minimum rate of sludge formation, estimates indicated

that the ammonia in the effluent would be replaced by 12,800 pounds per day of sodium and 16,300 pounds per day of chloride, originating from the stripping circuit. Sodium chloride was therefore environmentally unacceptable.

One solvent extraction process then remained, which would allow continued use of the existing process equipment. It would require a change from use of the tertiary amine presently employed, to a quaternary amine named Aliquat 336. The major advantage of the quaternary amine is that it may be stripped of its uranium using a sulphuric acid solution, thereby eliminating ammonia and avoiding the use of sodium chloride. Laboratory testing of the solvent again showed, however, that sludging at organic aqueous interfaces, in a modification of the Rabbit Lake solvent extraction plant, would be severe. Chemically, the amine was also less selective, with the result that arsenic in particular loaded onto the solvent and would have to be scrubbed in a significant plant addition. Both the kinetics raction and stripping were significantly slower than the tertiary amine, so that additional solvent extraction cells would be required. While the quaternary amine therefore was environmentally acceptable, it was less than satisfactory as a possible alternative to the existing process.

One laboratory test work programme, in its inital stages, however, held some promise of success. It involved solvent extraction using the existing solvent, but stripping with a strong sulphuric acid solution. Although initial results were encouraging, the approach was unconventional. Between June and October 1980, a considerable amount of test work was completed at Hazen Research Incorporated, which eventually established the viability of the process. It is now intended to make the minor modifications which will be required to convert to a strong sulphuric acid stripping circuit.

The operating conditions for the extraction section of the solvent extraction ion exchange circuit will remain unchanged.

The sulphuric acid stripping solution will have a concentration of 400 g/l sulphuric acid and will be advanced through the stripping circuit at about 17 igpm, approximately one third of the flow rate required for ammonium sulphate stripping. Five mixer settler stripping cells are required, so that one extra cell must be constructed in the solvent extraction area.

Pregnant strip solution presently contains approximately 15 to 20 g/l of U_3O_8. Strong sulphuric acid stripping will produce a pregnant strip solution which will contain 100 to 125 g/l of U_3O_8. That solution will be diluted with water to approximately 25 g/l as feed to the strip solution purification circuit.

See Overhead 3 (next page).

Table 4

Distribution of U, As, Mo, Zr, Si, and Bi in Alamine 336/H_2SO_4 Strip SX at 57 Organic Cycles - Collins Bay Liquor

	Assay, g/l							
	SX Feed	Raffinate	Pregnant Strip	Loaded Organic	Stripped Organic	% Extracted	% Stipped	Pregnant Strip Ratio Impurities/100 U

SiO_2	0.46	0.45	0.037	<0.01	<0.01	< 5	>50	0.04
Bi	0.0032	0.0024	0.007		<0.02			
H_2SO_4	10.0	12.0	293					
Cl	1.52	1.40	2.55					

Overhead 3 shows a typical distribution of major dissolved ions throughout the various products of a continuous laboratory solvent extractive. It demonstrates good selectivity for uranium, but poor rejection of, in particular, arsenic and Molybdenum. If allowed to pass to the precipitation stage, they would precipitate to some degree with the uranium, producing the maxima specified by our refinery. A strip purification stage is therefore included in the modified flow sheet. The first stage in the purification process will be the precipitation of zirconium, as zirconium phosphate, by the addition of phosphoric acid to a concentration of 0.5 g/l. The zirconium phosphate precipitate will be filtered from the eluate and pumped to tailing neutralization.

The filtered elute will then pass into a system of agitated tanks, where arsenic will be precipitated as ferric arsenate, by the addition of ferric sulphate, followed by the pH controlled addition of slaked lime to an approximate pH of 3.5 and magnesium hydroxide to an apporxinate pH of 3.8. The solution and precipitated solids (or iron cake) will pass to a thickener, from which the underflow solids will be removed. Since the iron cake will contain a minor amount of precipitated uranium, it will be leached with pregnant aqueous solution from the overflow of the first C.C.D. thickener, for uranium recovery. The leach iron cake will then be pumped to the clarifier, as show on the flow diagram, so that the solubilized uranium may be recycled to the solvent extraction circuit for recovery. The ferric arsenate eventually leaves the circuit, in the tailing stream from the C.C.D. circuit.

In the present circuit, anhydrous ammonia is used, not only as a reagent for stripping but also for precipitation. In order to entirely eliminate its use in the Rabbit Lake mill, and to avoid precipitating molybdenum and silica, it will be replaced by the precipitant, hydrogen peroxide. Magnesium hydroxide will also be used to maintain the pH in the range 3.5 to 3.8 throughout the precipitation. Because a continuous hydrogen peroxide precipitation system has not been developed to date, the new system will be a batch process. When

precipitation is complete, the solution and precipitated solids will be pumped to the yellow cake thickener, from where washing and drying of the product will be carried out as currently practiced. The spent eluate, from the yellow cake thickener, will be pumped through the existing sand filters, for the recovery of any entrained product solids, and then to tailing neutralization.

Almost five years of operation of the existing tailing disposal and effluent treatment at the Rabbit Lake mill has demonstrated its efficiency to produce an environmentally acceptable effluent in every respect except, for its ammonia content in the future, circuit modifications will eliminate the ammonia completely.

Two additional soluble contaminants must, however, be removed from the effluent, when processing ore from the Collins Bay B-Zone. They are arsenic and nickel and their maximum allowable concentrations in the final effluent are 0.5 mg/l in each case. The effluent neutralization has been examined, to modify it so that it will effect that removal.

Arsenic may be precipitated from tailing slurries and from the ion exchange barren solution as either ferric arsenate or calcium arsenate. Tests, which have been completed to determine the potential for redissoltuion of each of those precipitates, have indicated that the former is less soluble than the latter. The modified process, therefore, will precipitate the majority of the arsenic in that form. The barren solution, which contains the majority of the arsenic, will be treated separately. The equipment will consist of a number of tanks, where a one percent mixture of sulphur dioxide from the existing sulphuric acid manufacturing plant, in air, will be sparged into the agitated solution, to ensure that all iron present in the solution is oxidised to the ferric state. Lime will also be added to maintain the pH at approximately 1.3. The pH will then be raised to 4.5, at which point the arsenic will precipitate as ferric

arsenate. The resulting slurry will pass to a solution recovery thickener, from where the solids will be pumped to a first stage neutralization circuit. The thickener overflow, if acceptable for reuse as wash in the C.C.D. circuit, will be recycled. Otherwise it also will be pumped to the first stage of the neutralization circuit.

In the first stage neutralization circuit, the discharge or discharges from the solution recovery thickener, will be combined with the underflow tailing slurry from the last C.C.D. thickener, and the pH will be adjusted to 4.5 with slaked lime. The slurry will be held at that pH for approximately one hour, to precipitate as much arsenic as possible as ferric arsenate. The slurry will then pass to the second stage neutralization circuit where the pH will be raised to 12.5 to 12.7 with slaked lime and retain for approximately two hours. Although no residual soluble arsenic is expected after the first neutralization stage, any arsenic which may be present will be precipitated by the pH adjustment. Nickel will also precipitate as a nickel hydrate, and achieve the required specifications for both dissolved arsenic and nickel. After two hours, the slurry will be pumped to the tailing impoundment area.

INTRODUCTION

Rössing Uranium Mine is one of the world's great mines and also a most interesting uranium recovery operation, first because of the large size of the operation, secondly because of the remoteness and aridity of the location, and because operating costs are comparatively low, despite the very low grade of the ore.

As in any other desert, water is a scarce and valuable commodity in the Namib desert where Rössing is situated. Water is supplied to Rössing from two underground rivers, both over 100 miles from the mine. Rössing's policy is to minimize water consumption as much as possible both on the basis of cost saving and in the national interest. This case study is an excellent opportunity to see what happens in an acid leach uranium plant when it is necessary to recycle a large proportion of the water.

Of particular interest at this operation are the following aspects:

1. Rössing Uranium milling operations consume about 30% of the amount of fresh water per ton ore milled that is consumed at comparable uranium operations where water is not in short supply.

2. The degree to which tailings reclaim water and seepage are recycled to the process and its effect on TDS buildup, scaling, and corrosion.

3. Water quality effects at every stage of the process are interrelated, sometimes yielding unexpected results.

4. Natural attenuation of contaminants in seepage from the tailings dam.

5. Control of scaling.

6. Control of corrosion.

7. Effect of recycling on the uranium recovery process.

8. Water/salt balance modelling.

CLIMATE

20mm rainfall per year. Hot summers with occasional 60 knot bergwinds; up to 3.0 m evaporation per year.

WATER CONSERVATION PROGRAM

The Rössing Uranium Mine and Mill are located in the extremely arid Namib Desert where fresh water is scarce. The establishment of the mine and the mill which required up to 30,000 m^3/d of water was a significant additional demand, for the area had to be supplied from wellfields in two subterranean rivers, the Omaruru to the north and the Kuiseb River to the south. To supply this amount of water, the South West African Department of Water Affairs constructed major pipelines and pumpstations across the desert and supplied the water on a toll basis. Well water from the Kuiseb and Omaruru rivers is also supplied to the towns of Walvis Bay and Swakopmund, as well as minor rural consumers.

PLACE FIX - RÖSSING URANIUM MINE

After overcoming initial plant problems, Rössing was, by 1981, in a position to expand its efforts to reduce water consumption, and a program was put into effect to find all possible ways to achieve what, at the time, must have looked like an impossible dream. The first step was to measure and analyze the water balance and to examine where recycle water could be used without seriously affecting the process. Since then, the main thrust of the water management plan has been:

1) To recycle as much water as possible.

2) To reduce and control resulting corrosion and metallurgical effects of recycling.

Before 1981, the only use made of recycled tailings dam water was to dilute tailings before pumping them to the dam to maintain velocity in the tailings line.

One major use of fresh water was in pump glands. All the pumpstations except one are now converted to use acidic tailings return water for this purpose.

At the tailings dam area two reservoirs were built, one for acidic tailings water and one for nearly neutral collected seepage. These dams are at an elevation from which water flows by gravity to the plant. Rubber lined and high density polyethylene pipes were installed for this purpose.

A major savings was found to be possible if 12-13,000 m^3/d tailings return water could be used to replace that much fresh water in the rod mills. RDS and seepage water were recycled to the rod mills. The water saving benefits were immediate. Apart from using less fresh water in the mills, the water level in the tailings dam has dropped, thereby reducing the surface area and conserving more water because of reduced evaporation.

DESCRIPTION OF RÖSSING URANIUM OPERATION

NUMBER OF EMPLOYEES 2,600

TONS MINED Approximately 1 million tons per week (including wasterock).

STRIP RATIO 2.5 to 1

MILLS Four Open Circuit 14'Ø x 20' Marcy Rod Mills

TONS MILLED

1984 Est.	38,000 Metric tpd
1983	37,800 Metric tpd
1982	39,000 Metric tpd

NET FRESH WATER CONSUMPTION AT MILL

	Ore Milled, t/d	Fresh Water Consumption, m^3/d	m^3/t Ore Mined
1984	33,000	15,000 m^3/d	0.39 m^3/t
1983	37,800	20,600 m^3/d	0.54 m^3/t
1982	39,000	25,700 m^3/d	0.66 m^3/t
1981	46,000	29,850 m^3/d	0.65 m^3/t

This compares with 1.3 - 1.5 t new water consumed per ton ore milled at a typical mill using a comparable process (acid leach + SX) near Grants, New Mexico, where there are no water supply constraints.

ANNUAL URANIUM PRODUCTION About 5,000 tons per year U_3O_8.

CAPITAL R350 million in 1976.

MINING METHOD

Open pit, drilling, blasting, and face shovel loading to 170 t haul trucks.

ORE TYPE

Alaskite intrusions in metamorphosed sedimentary ocks. Some of the metasediments are high in carbonate.

METALLURGICAL PROCESS

The process is schematically shown below: crushing, grinding, leaching in sulfuric acid with MnO_2 oxidant, and cyclone removal of sand which is washed by rotoscoops. Slimes are washed by CCD followed by ion exchange, primary U_3O_8 recovery, and purification concentration by SX. Uranium is precipitated as ammonium diuranite and $(NH_4)_2SO_4$ recycled to the SX strip circuit.

PRODUCTION REQUIREMENT

With the current state of the uranium market, it is no longer necessary for Rössing to achieve the maximum production of which the plant is capable. Minimizing costs is the dominant management objective.

DAILY PULP TO TAILINGS	40,000 m^3/d
ORE DENISTY	2/7-2.7
MILLS	Four Rodmills on 2 Modules

GRIND

Grinding at 76-78% solids, residence time 4½ minutes, yields a course grind: 100% - munus 6 mesh, 30% plus - 20 mesh, mean size - ±0.7 mm.

RÖSSING URANIUM MINE

LEACH TANKS

On each module there are six mechanically agitated leach tanks in series, each fitted with 350 HP Lightnin gearboxes and motors. Initial solids settling in the tanks was overcome by extending the impeller blades to 5.1 m dia. and changing to a peripheral speed of 254 m/min. The impellers are rubber covered, and pulp is transferred via upcomers.

LEACH EXTRACTION 90%

LEACH CONDITIONS

Leach at 72% solids; average retention time - 8.6 hours. Leach time is regulated by bringing leach tanks on or off line. There is an economic balance between additional recovery and extra acid consumption with increased residence time. Leach temperature has dropped from 48-49°C to 38-39°C as a result of recycle water use. Here, too, there is a tradeoff in terms of reduced acid consumption.

ACID CONSUMPTION

Actual acid consumption is currently about 20 kg H_2SO_4/metric ton of ore. Rossing manufactures most of its own acid requirements on site from local pyrite.

The acid consumed depends on several factors but mainly on the acid consuming minerals present in the ore. This property of the ore is expressed in terms of an empirical factor known as 'Calc Index.' To determine calc index, an ore sample is crushed and ground, and an aliquot agitated in a beaker of acid. By back titrating the residual acid, an index which relates to the acid comsumption of the ore is determined.

The acid consumption of the ore is an important factor in considering the quality of recycled solutions since for every ton of ore leached, 40-50 lbs. of sulphate is introduced into the solution. Excessive acid addition may also have an effect on metal ions other than uranium that are leached--certainly more calcium is dissolved.

Small scale heap leaching tests were carried out on ores with calc indexes of 50-60 kg/t which indicated an acid consumption of less than 30 kg H_3SO_4/t. In one test, an ore with a calc index of 45 gave 40% extraction over 1½ months at an acid consumption of 7 kg/t using return dam dolution. Test work on the subject is continuing.

AFFECT OF TEMPERATURE ON LEACHING

Note: Not to Scale; qualitative data only.

EFFECT OF RECYCLING ON LEACH

There are three advantages in using return dam solution for milling and leaching:

1) Reduced overall acid consumption.
2) Recovery of some uranium values from RDS
3) Reduced water consumption.

Because RDS cannot be passed through heat exchanges, it is added directly to the mills without preheating. One effect has been a drop in temperature in the leaching step from the original 48-49°C. The result has been a drop in acid consumption. The effect on uranium extraction is negligible.

Solar heating of RDS using black plastic pipes and also solar brine ponds have been considered but in little detail.

SAND-SLIME SPLIT

Sand and slime are split using cyclones with two stages of rotoscoops to wash U_3O_8 values and residual slime from the sand in the cyclone underflow.

SOLID-LIQUID SEPARATION

The CCD train consists of four 42.67 mØ Envirotech thickeners in parallel as first stage thickeners followed by four 68.6 mØ Dorr-Oliver thickeners to provide 5 stages of CCD using the eight thickeners. After washing the slimes by CCD, final underflow is diluted with RDS, recombined with the sand fraction, and pumped to tailings. CIX Barrens are recycled to the tail end of the CCD circuit and rotoscoop circuits for use as wash solution. Feed density of pulp to the CCD is at SG 1.2-1.3. The ore has SG 2.6-2.7. Underflows have 45-47% solids, and the CCD overflow solution runs 1,200 ppm suspended solids.

CIX ADSORPTION

The Porter CIX System installed at the main plant at Rössing treats over 80,000 m^3/day of pregnant solution fed with a tenor of approximately 160/180 ppm U_3O_8. The pregnant solution flow is split equally between four CIX lines.

Barrens from the CIX plant in 1979 were reported as 8 ppm. Details of the design and operation of this circuit with its rectangular adsorption tanks were provided by P.

Vernon in a paper presented in 1979 at a conference in South Africa which can be made available to sponsors on request by RANDOL INTERNATIONAL LTD. In recent months, barrens have been up to 15 ppm, but much of this is recovered ultimately through RDS recycling.

Feed to the CIX plant in 1984 contained some 800 ppm solids. These solids tend to carry over via the preg eluate to the SX plant where they cause a problem.

Loaded resin in 1979 contained about 27 g U_3O_8/l.

During the 1984 visit, it was found that a regular cleanout of solids from the CIX adsorption system is needed to maintain uniform solution flow.

Solution enters each CIX contactor via a fiberglass distributor.

CIX adsorption performance has deteriorated as shown by the average preformance data provided below with recovery across the CIX plant dropping from 97% to 92.5%.

	Preg Feed (ppm U_3O_8)	CIX Tails Solution (ppm U_3O_8)
1980-81	190	5 ppm
1982	200	About 9 ppm
1983	160	8.5 ppm
1984	160	5-12 ppm

This data should, however, be viewed in conjunction with volume of solution throughput, resin type, and inventory changes, frequency of elution, frequency of acid washing, resin consumption, and changed water quality due to RDS recycling.

RESIN TRANSFER

Resin is airlifted from the lead CIX adsorption tank to the resin transfer sump and pumped via a WEMCO centrifugal vortex pump to the loaded resin storage cone located above the three elution vessels. The storage cone is fitted with a Dorr Oliver 60 mesh wedgewire DSM screen and a water spray. Screen underflow is returned to the No. 1 adsorption contactor.

CIX ELUTION

Loaded resin is gravity fed to one of three elution columns, each being totally independent of the other. A six-step elution cycle is employed as illustrated by the elution curves provided in P. Vernon's (1979) paper.

RDS INFLUENCE ON CIX PLANT

Recycling acid, sulphate, and chloride-rich RDS to the mill results in five main influences on the CIX plant.

- Competition with U_3O_8 for loading on IX resins by $SO_4^{=}$, Fe^{+3}, Cl^- and other dissolved species.
- Reduced solution volume throughput through the CIX unit due to jarosite scale buildup in the barrens lines (now controlled by the use of pigs).
- Risk of enhanced corrosion due to jarosite buildup where metal is unprotected by rubber or polyurethane.
- $[Cl^-]$ has risen in the eluate, too, and could be expected to result in enhanced corrosion of screens in the adsorption and elution sections.

There is not much that can be done to counteract the competition effect for adsorption sites on the resin. Slight alleviation might be possible by optimizing resin selection for use under the changed set of circumstances and more frequent elutions. This means having to live with lower U_3O_8 adsorption loadings on the resin, lower tenor eluates, and a generally reduced capacity of the IX plant, which is not a major concern while operating at reduced throughput.

The Rössing pregnant solution has, since 1980, had a fairly constant zinc content of about 37 ppm. The most probable source of this zinc is thought to be the calcine arising from roasting of pyrite for acid production. There was a concern that this might have a detrimental effect on CIX performance, but as yet no evidence of this has become apparent.

The CIX barren solution uranium tenor of 5-15 ppm U_3O_8 and a current recovery into eluate of only a little over 92% is poor by comparison with most plants around the world. The performance of the IX plant has been under scrutiny ever since the operation started and with greater intensity of late. Some of the factors that have been examined are TDS buildup in preg solution, SiO_2 fouling, ore type, and manganese levels in solutions.

- SiO_2 in the preg solution has increased steadily since 1980.

	March, 1979	February, 1984
SiO_2 (ppm) in Preg Solution	427	950

Resin regeneration frequency has been adjusted to keep resin SiO_2 levels below 2,000 ppm. However, the cost of regeneration with 4% and 1% NaOH solution is high and lately, regeneration frequency has been cut back without adverse effects on silica loading on resin. The cost of regenerating the resin has been cut by 40% since 1983 by optimizing frequency and procedure.

After increasing the frequency of elutions, the SiO_2 buildup rate on the resin has dropped noticeably and considering the higher levels of SiO_2 in the pregnant solutions, it is likely that the SiO_2 passes through with eluate to the SX plant and may end up in CRUD.

Rössing ore contains variable amounts of cordierite gneiss containing pyrrhotite which seems to be directly related to barrens loss and SiO_2 levels in the pregnant solution. Certainly the recycling of RDS has an influence on SiO_2 in the pregnant solution and, therefore, also on the relative merits and costs associated with different resin types.

AFFECT OF ORE CHARACTERISTICS ON SiO_2 BUILDUP ON RESIN AND BARRENS LOSS

(Qualitative Data based on freehand sketch)

RESIN LOSS

The CIX plant has a resin inventory of 750-800 m^3. Resin losses amount to ±17 m^3/month, i.e., 25% of inventory per year, i.e., 8 parts resin per million parts solution treated.

RESIN SELECTION

In March ,1984, Dowex XFS resin was the predominant resin in use; it cost R5800/m^3 at that time (U.S. $0.82 = R1.00).

Sentrachem-KOP resins had been tested in the laboratory and had a lower price of R4,800/m^3. This resin was found to have a comparable uranium loading capacity and a better resistance to osmotic shock, but its attrition properties proved poorer than the Dow resin.

Current thinking has been that the major contribution to resin loss is attrition rather than osmotic shock.

SX PLANT

The SX plant at Rössing was originally intended for operation with the organic phase continuous in extraction. Experience was, however, that the continuity flipped to aqueous very readily and for ease of operation, it has been allowed to run that way for the past six years.

A model of the SX system was built for laboratory improvement development aimed to:

- Improve Phase Separation
- Reduce Organic Entrainment

A crud treatment tank is installed in the system.

Crud is treated with acid.

Rössing looked at centrifuging crud but at a cost of R70,000 a centrifuge could not at the time be justified. .

Most organic losses are lost via raffinate to fresh eluant to resin to barrens to CCD wash to tailings dam.

The ion exchange eluate at 100 g H_2SO_4/l has a high chloride level as well and would be expected to corrode stainless 316L steel. However, due to some passivation mechanism that is not yet understood, this does not occur in the elution system or the SX plant. The phenomenom has been reproduced in lab corrosion tests.

CORROSION

Recycle of RDS to the process results in several points where corrosion has been enhanced, due mainly to higher chloride levels in an acid pH and to corrosion associated with jarosite scale associated with bacterial processes.

Another factor that may affect corrosion is the high level of fluoride in the RDS and seepage at 98 and 42 ppm respectively. At these levels, fluoride-related corrosion deserves some attention, especially where elevated temperatures are employed. A consultant who is interested in fluoride induced corrosion is:

JIM MAVIS
CH2M Hill
1500 114th Avenue, S.E.
Bellevue, WA 98004
(206) 453-5000

This factor could become more important if a way is found to heat the RDS solution prior to addition to the rod mills. There are ways to remove fluoride from water which could be considered if this was found to be a factor.

The following general observations on corrosion risks and preventive actions have been accumulated by Rössing engineers:

ROD MILLS

In early 1984, 81% of the water needs in the grinding circuit were provided by recycled water of which 58% was RDS (return dam solution), and 23% was recovered tailings dam seepage water. One deleterious effect is the increased risk of corrosion of the rod mill shells and actual corrosion of the linings and rods. These effects were still under investigation to determine their precise cost and to find alternative ways to reduce the impact.

ROD MILL SHELL

The use of acidic high TDS recycle dam solution in the rod mills was anticipated to be a cause of corrosion. The neutralizing characteristics of the ore raise the mill solution pH from 2 to 4.5, but there is, nonetheless, a pH profile along the 20' lengths of the mills.

Experiments were carried out with mill shell coatings eventually settling on an epoxy tar layer on the inside of the mill shell. The product used is an amine-cured cold tar modified epoxy material sold by Plascon Paints (Pty) Ltd. in South Africa under the product code EPD-100 which was applied by Rossing's protective coatings department.

The epoxy tar coating was spark tested to be pinhole free; then tested at 30% and 60% RDS recycle usage followed by inspections. All four mills have been coated.

A physical ultrasonic inspection procedure to test coatings is offered by two companies in Johannesburg, including Engineering Inspection Company (Pty) Ltd. Inspection is now done in-house.

ROD MILL RODS

Consumption of rods has increased by about 20% when 1984 consumption is compared to 1980. 50-60% of the water used in the mills is now acidic RDS, but this is not the only factor involved. In particular, the milling rate has decreased somewhat which certainly contributed to the increased consumption. The Rössing estimate is that about half of the increase can be directly attributed to RDS.

Tests have been carried out with heat treated steel rods which are imported. Although a reduction in steel consumption of some 19% was observed with the heat treated rods, their high cost at present renders them unattractive economically.

MILL LINERS

In the early years of the life of the mine, the standard mill shell liners used at Rössing were two-piece, forged liners. The life of a set of these liners was of the order of two million tons milled.

In 1981, a test was started with heat treated high chrome, cast liners supplied by Foundaries Magotteaux. These test liners ran a mill fed with 100% fresh water. The test set of liners gave a life of 5.6 million tons, and all mills were progressively changed over to these liners.

The installation of the second set of Magotteaux liners coincided with the introduction of a significant quantity of RDS into the grinding circuit and with a slight reductionin milling rate. Liner life experienced today is variable but well below the 5.6 million tons shown by the first set of Magotteaux liners. As with rods, it is difficult to attribute the proportion of this reduction to RDS and to other causes, but Foundaries Magotteaux metallurgists are convinced that corrosion does play a part.

CCD RAKES AND MECHANISM

The leached pulp at about 3.5 g/l H_2SO_4 comes in contact with the CCD thickeners with rakes and mechanisms constructed of stainless steel 316L. RDS recycle contains high Cl^-, and ferric concentrations would accelerate corrosion of these components. Numerous corrosion tests were performed based on advice by the Resource Conservation Company International of Seattle, Washington. These tests are discussed elsewhere in this report, but it was found that stress corrosion did not occur and at very high chloride levels, pitting and crevice corrosion would occur at about 3.5 g H_2SO_4/l.

Cost estimates of replacing the CCD thickener rakes and mechanisms with superior corrosion-resistant stainless steels were obtained from Envirotech and Dorr Oliver, but these were very expensive.

Experiments were conducted successfully on coating exposed stainless 316L surfaces with abrasion-resistant polyurethane foam coatings. These experiments were extended to the actual plant with encouraging results.

Polyurethane coating applied as a mixture of two components manufactured by Bayer Leverkusen, West Germany, has been used for coating the rakes. This step was taken with consultant guidance from:

MICHAEL A. BRETT AND PARTNERS
Post Office Box 61872
Marshalltown 2107
South Africa
(011) 803-2273
Dr. Colin E. Alvey, Partner

The polyurethane coatings were applied on different rakes by two different contractors who specialize in polyurethane corrosion protection. The first two thickener rakes were coated by:

RÖSSING

ATLAS FOAM (PTY) LTD.
Post Office Box 2268
Trekker 1547
Brakpan, South Africa
(011) 558-504
Graham Pole

ATLAS FOAM uses a non-solvent method of applying foam through a nozzle that mixes the components at 4-5 l/minute. The two components are polyether and Isocyanate mixed 100 parts:75 parts.

The electronic mixer can apply to any thickness. e.g., 3 or 4 mm in sequential layers without waiting for the solvent to dry. Because of the configuration of the thickener rake, there is a high wastage of material during the application. ATLAS FOAM took six days to complete the job on the second thickener job, including spark testing. The cost of these coatings is normally R20 per m^2 per mm thickness ($1.30/$ft^2$ per 4 mil thickness) which is comparable to rubber coating in price, but much quicker to apply and more appropriate for the application (according to the vendors).

Specifications of the Polyurethane coating are:

Shore A Hardness	65-70	W. German DIN 53505
Density	0.9	W. German DIN 53479
Strain	100%	DIN 53504 MPa 4
Strain	300%	DIN 53504 MPa 7
Tensile Strength		DIN 53504 MPa 10
Elongation		DIN 53504 600%
Tear Propagation Resistance		DIN 53515 16
Impact Elasticity		DIN 53512 45%
Abrasion Resistance		DIN 53516 mG 130

The product expert at Bayer Leverkusen is Mr. Vogel who has advised ATLAS that the coating is good for use up to 80°C with temperature surges to 130/140°C, but he would be nervous about continuous service at 120°C.

ATLAS FOAM (PTY) Ltd. claims that their coatings are pinhole free because of the solvent-free application. Sometimes thin spots in the corners and nooks are difficult to avoid using spray application, but the material is also trowlable.

According to ATLAS FOAM, there may have been isolated pitting corrosion the first rake; however, there has been no corrosion on the second because they were more experienced for their second rake job.

ATLAS FOAM (PTY) Ltd. claims that their BAYER polyurethane material is cheaper than the UNIROYAL polyurethane system which costs R18-19/kg compared with the BAYER product at R13/kg (prior to the recent devaluation of the Rand).

The second two thickener rakes were polyurethane coated by an Australian company:

WEAR RESISTANT MATERIALS (PTY) LTD.
2 Kelsey Place
Asquith NSW 2078
(02) 476-5655
Telex: c/o Chatswood Public Telex Office
WRM POL AA 70410
Ian Lyon, Managing Director

WEAR RESISTANT MATERIALS (PTY) LTD. use a solvent based polyurethane application using standard spray equipment and polyurethane imported from Australia.

The Rössing Uranium Mine subsequently coated the fourth thickener themselves.

CIX PLANT

Apart from the ion exchange effects, the higher Cl^- levels can be expected to [illegible] .ce corrosion of stainless steel.

Elution columns were rubber lined. SX solvents loosened the rubber steel bond. Now the mild steel shell is being coated with FRP as needed--so far, 5 out of 12 columns have been lined in FRP, of which one has been in service for two years without attention.

PUMPS

Tailings and solution pumps for an operation this size require a large amount of gland water. For example, the tailings pumps each require 1.2 l/sec of gland water, and there are 10 of them in each pump station--i.e., 160 gpm per pumpstation is required.

Rossing has converted to RDS water for pump glands which is not recommended by pump manufacturers. RDS with its low pH and high chloride level also contains about 1,000 ppm suspended solids which caused increased abrasion on the pumpshafts and sleeves.

To overcome this, Rössing has fitted stainless 316L steel sleeves over the mild steel shafts of the pumps. A major cause [illegible] ...ure resulted from abrasion through the gland

seal due to the high solids. Before using RDS for pump shaft lubrication, the shaft sleeve lasted 1,600 hours between replacements. After RDS, life was reduced to 1,200 hours, at a cost of R1060 each plus labor. This is a possible application for plastics.

PUMP MODIFICATION FOR RDS AS GLANDWATER

An innovative water filter was installed on an experimental basis; This was a Filtomat filter unit manufactured and offered by:

BATEMAN EQUIPMENT LTD.
Post Office Box 565
Boksburg 1460
South Africa
(011)899-9111

The Filtomat unit installed at the time of the visit was a rubber lined mild steel unit fitted with a 20 micron screen. A second unit fabricated from stainless steel was on order to test as a means of removing solids from pump gland water. The stainless steel Filtomat unit sells for R12-13,000. In the Rossing application, the units were not satisfactory as a high pressure, not available on the system, is required for efficient filtration and backwashing.

SCALE

Leaching Tanks

Jarosite Scale has built up on the bottom of the large leaching vessels particularly where the walls meet the floor. This did not occur until after tailings solution was recycled, and is still not a serious problem.

BARREN LINES

Following the introduction of return dam and seepage recycling, iron silicate jarosite started to build up in the barren lines, particularly remote from the pumps.

Several workers link jarosite formation with bacterial action, and a literature survey suggested that this was a likely cause at Rossing. Dr. E. Liversley-Goldblatt and the Gencor Group Laboratory identified a thriving bacterial community in the recycled solutions, including thiobacillus ferroxidons which is associated in the literature with jarosite formation.

Jarosite buildup in the barren lines restricts solution flow significantly. Rössing's response is to remove the buildup periodically by mechanical means. Experiments with sandblasting the interior of the pipes were unsuccessful due to damage to the rubber lining of the pipes. Polymer pigs with abrasive surfaces have, however, been successful, and these are put through the lines whenever the flow is observed to have decreased.

RANDOL IDEAS/COMMENTS FOR JAROSITE CONTROL

- Jarosite scale creates a highly corrosive environment when in close proximity to steel. Metal concentrations in the jarosite create electrolytic cells with steel as the other electrode resulting in its corrosion.

- One possible way to kill the bugs may be through sterilization of the return solution with ultraviolet light. There are innovative transparent plastic tube devices for this.

- A major water treatment company pointed out that biocides are essential ingredients in many scale control and corrosion inhibitors. Possibly, dosing the RDS dam or return line with biocide could prove helpful.

OTHER WATER USES AT RÖSSING URANIUM MINE

1) Water for Environmental Control
   - Water sprays to control dust at the primary crusher. 250 m^3/day water is used for this purpose.
   - 3,000 m^3 water is used for dust control in the mine on roads and muck piles.

2) Treated Water used as Boiler Feed Water

3) The Rössing Uranium Mill water consumption is:
   - 0.39 m^3 fresh water per ton milled (1984) = 87 U.S. g/st = present.
   - 0.54 m^3 fresh water per ton milled (1983) = 108 U.S. g/st.
   - 0.66 m^3 fresh water per ton milled (1982) = 132 U.S. g/st = historical.

WATER CONSERVATION STEPS

4) Water use was originally 30,000 m^3/day when fresh water was applied to every use except tailing transport. Since then, it has been cut down to 14-15,000 m^3/day.

5) Seepage water collected from below the tailings dam has an improved quality compared with the dam water itself, it is relatively low in particulates and is used for gland seal water for the pumps.

6) Seepage and return dam solution is used in the rod mills. This has required acid proofing of the mill shells.

7) Return dam solution is used for gland seal lubrication in some pumps after acid proofing pumps, glands, and seals.

8) Since July, 1983, the rodmills were converted so that 80% of their water needs are met by tailings dam reclaim solution.

9) Late in 1984, seepage water was to be used for general washdown.

10) A water manager is employed to keep detailed track of water usage. Every operator is monitored, based on the size of his pipes and pumps. The water manager alerts operators when their water consumption is high. This is an essential measure as unless operators are constantly watched and the importance of saving water impressed on them, this remains a low priority item to them.

WATER BALANCE MODEL

A water balance model for a metallurgical plant must also compute the salts balances. Dames and Moore, Denver, Colorado, has assisted in the water model for the complete mine, mill, tailings dam system. The Rössing staff includes several who are adept at computer applications, and the water-salt balance model now seems to be capable of accurate predictions of water quality.

CLHORIDE BALANCE

Chloride levels in the RDS are one of the major causes of corrosion and a competitive ion in the CIX adsorption circuit.

CHANGING [Cl^-] LEVELS IN PROCESS SOLUTION

1979	500 ppm in Preg Solution
March, 1984	1,400 ppm
[1] December, 1984	1,500 ppm
[2] Ultimate	1,100 ppm

[1] Evaporation of tailings result in higher concentration.
[2] As the tailings dam gets smaller, evaporative losses will be smaller compared with fresh water intake.

The dam water balance model has been programmed into Rössing's mainframe and DRS 50 Computers. To date, the model has been able to give a good prediction of water quality. The engineer working on this model is Brian Olver.

One assumption is that as the chloride concentration in solution increases, a smaller percentage of the Cl^- in the ore will be leached. The main input of chloride is, however, in the fresh water which contains 200-300 ppm chloride.

FRESH WATER REQUIREMENT

Historically (Max.)	28-30,000 m^3/d	0.7 m^3/t Ore
1984	15,000 m^3/d	0.4 m^3/t Ore

COST OF WATER

The unit price of water supplied to Rössing has increased since 1978 by 86%. However, due to the economy measures, the actual gross cost of water to the company has increased by only 16%. To bring about these savings, substantial capital expenditure has been justified.

WATER QUALITY

Fresh water quality, as delivered for December 1981/82/83, is shown below:

WATER QUALITY - FRESH WATER DELIVERED TO OPERATIONS

	December 1981 (ppm)	December 1982 (ppm)	Decmber 1983 (00m)
pH	8.3	7.9	8.4
Conductivity (Micromhos)	1,200	1,250	1,200
Total Dissolved Solids	888	828	750
Suspended Solids	8	2	
Total Hardness, ($CaCO_3$)	279	286	
Calcium Hardness, ($CaCO_3$)	180	187	
Magnesium Hardness, ($CaCO_3$)	99	99	
Total Alkalinity, ($CaCO_3$)	195	194	196
Chloride, (Cl^-)	280	250	240
Sulphate, ($SO_4^=$)	99	81	54
Fluoride, (F^-)	0.53	0.5	0.4
Nitrate, (NO_3^-)	24	12	15
Ammonia, (NH_3)	-	1	1
Iron, (Fe)	0	0	
Manganese, (Mn)	0	0.1	0
Potassium, (K)	16	14	11
Sodium, (Na)	136	150	140
Silica, (SiO_2)	20	23	
Arsenic, (As)	0.003	0.003	
Uranium, (U)	-	-	-
Calcium, (Ca)	72	75	80
Magnesium, (Mg)	24	24	21
Aluminium, (Al)	0	0	
Radium, (Ra^{226})	-	-	-

FRESH WATER CONCLUSIONS

- Based on the estimated cost of fresh water consumption, there appears to be a significant cost incentive in reducing fresh water consumption.

- Rössing is fortunate in that the price of their water is not structured to reflect the fixed costs of the pipeline and pumps and so does not increase as consumption drops.

DAILY WATER BALANCE — UNITS IN m³

APPENDIX 7.33

FRESH WATER USAGE

A typical 1983 daily water consumption distribution is shown below.

645 m^3/d	Potable Water to Mine - Potable and Toilets
495 m^3/d	to Open Pit Mine Toilets and Potable
1,226 m^3/d	to Crushers
2,733 m^3/d	to U Recovery Plant
3,219 m^3/d	to H_2SO_4 plant
3,917 m^3/d	to Plant Wash and Flush
1,287 m^3/d	to MnO_2 Rodmill
2,130 m^3/d	to Rodmills (731 m^3/d with Ore from Crusher)
15,652 m^3/d	to U-Plant
632 m^3/d	to Daily Paid Housing
1,719 m^3/d	to Arandis Village
1,030 m^3/d	Unaccounted for
19,033 m^3/d	TOTAL

A current and detailed water balance is maintained which is essential in order to improve and monitor water conservation management.

WATER TREATMENT

The only active water treatment plant used at Rössing is for desalination of boiler feed water.

In 1981, a study was undertaken by the Resource Conservation Company International which reviewed ion exchange, reverse osmosis, evaporation, neutralization, and EDR at the Rössing Complex. None of these has been found to be cost effective to date.

Rössing loses approximately 9,600 m^3 water/day to evaporation. It is found in evaporation pan experiments that effluent evaporation rate decreases with time as shown in the following graph. Rössing has concluded that the reduced evaporation rate is due to wind sheltering effects of the wall of the tank.

TANK EVAPORATION EXPERIMENT

In experiments at North American, operators found the same effect but concluded that the increasing salinity was responsible for the reduced evaporation rate.

The tails dam water level has dropped due to recycling and evaporation losses reduced.

Evaporation losses at Rössing are on occasions very high. The evaporation rate typically runs 8-9 mm per day (120 inches/year). Over 9,600 m^3 per day of water is lost to evaporation. The water surface in the tailings as of early 1984 was 120 hectares--1.2 million m^2 in extent.

A literature search was undertaken on evaporation. Several experiments were undertaken to cover the tailings pond including the installation of 12 hectares of floated plastic sheeting. Somehow, water was blown on top of the sheeting.

The tentative conclusion so far is that the best way to reduce evaporation is to make the water pond deeper with a smaller surface area. The area has been reduced slightly because of the bigger water off take and increased recycle which has reduced the water inventory in the tailings impoundment. Research is continuing in this area. Tailings deposition is so directed as to minimize surface area.

SEWAGE

There are four sewage plants located at Rössing:

Mine Changehouses
Village Housing
Day Rate Employee Housing
Rössing Country Club

The sewage treatment areas are monitored to determine that treated sewage water meets effluent standards.

GROUND WATER QUALITY PROTECTION

At any mining operation today, protection of the quality of the local ground and surface water is of major importance. Rössing is no exception. However, the scale of operations required to achieve this is unusually great.

The prime source of potential impact on ground water quality is the heavy metals and radionuclides contained in the acid solution within the tailings dam. The tailings disposal area is situated upon calcereous sediments, and the sands with which the tailings dam walls are constructed are also acid consuming. Seepage of acid solution through the wall and through the underlying sediments is, therefore, permissible as the radionuclides and heavy metals precipitate virtually completely. The same is not, of course, true of the anions, and it is necessary to recover seepage water from the sediments and from the alluvium of the (normally dry) water courses of the area. A complex of more than 80 monitoring and recovery boreholes are located around the tailings dam. One of the seepage recovery installations, that in the Pinnacle Gorge, is illustrated in the accompanying figure.

The groundwater of the area is extremely brack, typically with a chloride content of over 2,000 ppm and a TDS in the range 4-8,000 ppm. Sulphate content is variable but relatively low, in the range 1,000-2,500 ppm. Tailings dam water, however, contains some 30,000 ppm sulphate and less than 1,500 ppm chloride. Any increase in the sulphate:chloride ratio in the groundwater quality monitoring boreholes is, therefore, a sensitive indicator of infiltration of seepage from the tailings dam and provides early warning of the need to install recovery pumps. Rössing, with assistance from Dames and Moore, has, during 1984, been developing a computerized model of the movement and quality of groundwater in the various geological structures of the area. Use of this in a predictive role will, in the future, permit even better groundwater quality protection and greater recovery of recycleable water.

By these methods, Rössing has been entirely successful in protecting the environment off its own property. This has been done to the satisfaction of the regulatory authority, the Department of Water Affairs, to whom comprehensive and regular returns are made.

Responsibility for the functions of environmental control and all aspects of water economy is vested in the Superintendent, Environmental Control and Water Management. He reports to the Assistant General Manager and has a staff of 15 dealing with a wide range of environmental concerns including dust, radiation, and noise monitoring as well as water quality and economy.

EFFECT OF RECYCLING ON WATER QUALITY

TDS in the tailings dam water has built up steadily. According to a computer model, this will increase to a point at which it will stabilize at 40,000 ppm TDS and 1,600 ppm Cl^-.

The water management plan called for a drastic drop in water consumption from 26,000 m^3/day to 14-15,000 m^3/d. This is resulting in a shrinkage in surface area of the tailings pond water surface. When this reaches a small size, it is likely that fresh water intake will have to be increased somewhat.

The change in concentration of various species as a result of recycling is shown below:

	Mn (ppm)	Cl^- (ppm)	$SO_4^=$ (ppm)	SiO_2 (ppm)	F^- (ppm)
July, 1981	1,890	820	20,264	324	115
December, 1981	1,925	880	20,647	320	98
July, 1982	2,450	930	20,903	340	52
January, 1984	2,550	1,220	30,273	No Data	102

AFFECT OF RECYCLING ON CORROSION: SUMMARY

ROD MILLS

Water recycling effects on corrosion of rod mill shells is likely to have been prevented by applying a special protective coating. Additional rod and lining steel consumption or conversion to more costly steels is an added cost resulting from water recycling.

CCD RAKES AND MECHANISM

Another area of concern is corrosion of stainless steel 316L components of the CCD thickeners which would be more susceptible to corrosion in the very low pH environment as chloride levels build up due to use of RDS. These components included the rakes and the central mechanism. Replacement of the rakes and mechanisms with ones fabricated from more corrosion-resistant stainless steels has been evaluated but would be expensive. Prior to this alternative, an attempt is being made to prevent corrosion of rakes by applying a protective abrasion-resistant coating of polyurethane discussed above which, to date, has after trial and error evolved to an effective measure.

ION EXCHANGE PIPING AND ELUTION CIRCUIT

The piping on the elution columns employed in the CIX circuit are fabricated from stainless steel. The elution components come in contact with solutions that have 100 g H_2SO_4/l. Recycling of RDS solutions results in an increase in $Fe^{3=}$ and Cl^- in the system which carries through to the IX eluates, and should result in enhanced corrosion, but this has not yet been observed. Repeated inspections have shown that the 316L stainless has not been corroded at all, contrary to expectation. Some kind of passivation mechanism must be occurring which has not yet been explained.

PINNACLE GORGE SEEPAGE COLLECTION

RDS AND SEEPAGE RETICULATION

Return dam solution and seepage are stored in separate reservoirs situated on an elevated point about one half kilometer from the plant. These reservoirs are built in tailings sand and plastic lined.

RDS is pumped from a station on the edge of the tailings lake to the reservoir via dense polyethylene pipes from whence it gravitates through pipes of the same material to its points of use in the plant.

Seepage is pumped from the various collection points to its own reservoir using a variety of pipeline materials.

Experiments are underway to use a spun polyurethane pipe coating. Two test sections of pipe have been installed, supplied by:

BOSWORTH PARABRASON (PTY) LTD.
Post Office Box 3705
Airode 1451
South Africa
(011)864-164318
Telex: 4-21208SA
Gerald Bosworth, General Manager

TAILINGS LINE

Tailings are pumped against a significant head so a high pressure line is needed. Steel pipes are used. These are protected against abrasion and corrosion by rubber lining.

PUMPSHAFTS AND SEALS

Pump Manufacturers do not recommend the use of low pH RDS water with high chloride levels for gland lubrication water. Increased abrasion on the sleeves and shafts of the pumps would be expected due to high suspended solids. Rössing built stainless steel 316L sleeves onto the pump shafts. Filtomat grit removal filters were installed on a test basis to screen RDS water for gland use at 50 and 20 microns.

The pumps require 1.2 l/second glandwater each, and there are up to 10 pumps at each pump station, which works out to 160 U.S. gpm per station.

Further protection had to be provided to protect pumps and concrete pads from RDS splashes which would also be corrosive.

CALCINE THICKENERS

The thickener rakes used on a calcine slurry after discharge from the acid plant at pH 2-3 are made of exotic stainless steel 704 or its Sandvik equivalents 2RD65, SAF2205, or Cronifer 1925 steel. This steel stands up adequately.

CALCINE REACTORS

Calcine is reacted in an acid brick-lined vessel, also with a lead lining using PTFE and stainless components and air agitation. Again, no impact due to recycling RDS in the U-plant would be anticipated.

CIX ELUATE AND SX PLANT

The CIX eluate which becomes feed for the SX plant and later raffinate contains 100 g H_2SO_4/l. This solution is high in chlorides too, yet no attack of stainless steel 316L is observed. The phenomenon was borne out by laboratory tests which indicate some passivation mechanism at work.

TAILINGS DAM

35,000 m^3/day of tailings pulp are transferred to the tailings impoundment via a rubber lined steel pipe. A flowrate velocity of 4.5 m/sec is needed to keep the coarser particles from settling in the line. Experiments are in hand to reduce velocity and pumps required.

A moving slurry at this velocity is certainly abrasive. The rubber pipe lining serves to protect as much against abrasion as corrosion. The entrained solution is likely to be very scaling as well as corrosive.

The tailings dam represents a large surface area for evaporation, especially in the arid, hot desert climate with not infrequent high velocity wind. Before RDS recycling was started, the tailings dam contained 14 million m^3 of solution which by March, 1984, had dropped to 8 million m^3, thereby reducing the surface area of the pond exposed to evaporation. The tailings dam water serves as a host to a bacterial culture believed to enhance scaling and corrosion phenomena in the U-plant when the RDS water is recycled.

The water balance around the tailings dam has not been completely defined as yet. DAMES AMD MOORE has been retained to help develop the model.

SUMMARY

RDS RECYCLE EFFECT ON PROCESS

Advantages

1) Reduction of acid consumption.

2) Recycled ferric ions.

3) Reduced water consumption cost which is significant.

4) U in RDS recycles to plant and is recovered.

Disadvantages

1) Higher TDS, $SO_4^{=}$, and Cl^- in preg solution reduces CIX adsorption plant capacity and increases operating costs.

   Possible answer: find a more selective resin or one that has a higher loading capacity or has improved kinetics.

2) Requires more frequent elution cycles.

RDS EFFECT ON PLANT OPERATION

1)	Pump Shaft Corrosion and Gland Seal Abrasion	Fit stainless steel sleeves to pumps. Filter particulate material from gland seal RDS water.
2)	Rod Mill Shell Corrosion	Epoxy tar shell coatings.
3)	Rod Mill Liner Corrosion	Live with increased liner cost or try out more expensive liner materials.
4)	Rod Corrosion	Enhanced rod steel consumption cost.
5)	Scale Buildup in Leach Tanks Reduced Capacity (Minor Effect)	Isolate tanks for regular cleanouts.
6)	CCD Rake Corrosion	Polyurethane coating application or very expensive rake replacement.
7)	CIX Adsorption Plant Scale Formation	More downtime plus labor costs to clean.
8)	Jarosite Scaling on Barrens Line; Reduced Capacity of CIX Adsorption Plant - Corrosion	Use abrasive polymer pigs to clean out the rubber lined pipe. Examine ways to clean bacteria in RDS which cause jarosite scale.
9)	Higher Cl^- in the Eluate Should Enhance Corrosion in Elution Plant and SX Plant Stainless Parts	Does not happen in practice. Some kind of passivation.

DATE OF VISIT	9 August 1984 At the time of the visit most of the experienced mill staff were away on vacation.	

INTRODUCTION

The Con Mine started operations at 50 tpd in 1938 and initially treated an arsenical sulfide gold ore by roasting and calcine leach. The operation expanded in stages. Since 1972 when the refractory arsenical ore was exhausted, a non-refractory ore has been treated by direct cyanidation.

The arsenic dusts collected from the original roaster were impounded in unlined ponds, and ultimately became recognized as an environmental liability. Cominco recently developed and implemented what appears to be a simple arsenic recovery process yielding a gold bearing residue for cyanidation.

Also, the Con mill now operating at 750 stpd is housed in the cramped original mill building and still uses several pieces of original equipment. Several innovative new items of equipment are being or have been installed and are of interest to determine how well they will perform in a commercial operation.

Items of particular interest at the Con Mine and Mill are:

GOLD RECOVERY

- Performance of a Japanese Tower Mill for ore grinding.
- Performance of Atara Air Cannon Mixers being retrofitted into obsolete existing agitators.
- Recovery of gold from arsenic plant residues.
- MnO_2 and fluorspar in the smelting flux.

WATER TREATMENT

- Decomposition of cyanide and arsenic plus base metal precipitation in the tailings pond effluent.

ARSENIC PLANT

- A process that is extremely simple on paper ends up requiring an investment of C$14 million to treat less than 30 stpd arsenic feed.

PLANT CAPACITY

750 stpd ore plus 5 tons per day arsenic plant residue. Average annual throughput is 650 stpd ore.

GRADE

0.4 oz Au/st (13.6 g Au/t).

RECOVERY

90-91% to yield 200-250 oz Au/day.

MINES

Ore is mined at the C shaft and the Robertson shaft. Workings currently extend to 5300 ft. below surface and are likely to be deepened to 5500 ft.

MILL DESCRIPTION

Mill throughput has grown in stages:

1938	40 tpd
1955	400 tpd
1965	450 tpd
1983	750 tpd

The latest expansion to 750 tpd came about with conversion of the mill to treat oxide ore.

Because of the cold climate all conveyers are completely enclosed and the mill building is weatherproofed and insulated.

Mill facilities are very cramped and the plant includes several old equipment items some of which have stood up to much wear.

The mill flowsheet is shown on the diagram inserted below with some changes: The Akins Classifier has been replaced by two 10" Ø cyclones and the 5' Ø x 9' AC secondary Ball Mill has been replaced by a Japanese Tower Mill.

Cyanide is added to the ball mill and the tower mill to allow grinding in cyanide, and the No. 2 and 3 thickeners have been removed to make room for a large leach tank that is to be fitted with ATARA Air Cannon Mixers. Cyanide is added in increments throughout the plant to maintain 0.6 lb CN per ton solution in all the leaching steps.

Minewater is used to mix the cyclone recovered sand fraction of tailings with cement for transport back underground at 60% solids.

Apart from the application of the tower mill and ATARA mixers for leaching, the circuit is a conventional crush - grind - leach - filter - Merrill-Crowe system. Another unusual feature seen more in Canada than elsewhere is the sequence grind in cyanide (leach) - decant of Preg 1 - agitation leach - filter for Preg 2 - repulp and leach - filter for Preg 3 - repulp and leach - filter for Preg 4. This is shown on the flow chart.

WATER BALANCE

The Con Mine is permitted to draw 1,600,000 m^2 water per year from the lake, which is 4,822 short tons water per day or 670 lgpm.

Based on fragments of information and the 1977 flowsheet an estimate of water balance is as follows:

Water Intake	Minewater	± 230 stpd	35 lgpm
	Fresh lake water to mill	1300 stpd	180 lgpm
	Fresh water to non milling		
	Total Permitted Water	4822 stpd	670 lgpm
Water Use in Mill	Barrens recycle to grind	540 stpd	
	Barrens to filter wash	1138 stpd	
	Minewater for sand backfill	230 stpd	
	Freshwater filter wash	330 stpd	
	Freshwater tailings repulp	1270 stpd	
Discharge	Barrens Bleed	90 stpd water	
	400 stpd slimes @ 25% solids	1200 stpd water	
	350 stpd sand @ 60% solids	230 stpd minewater	
	750 stpd	1520 stpd	

Total allowable consumption of water would work out to about 6 tons water per ton ore milled, but how much is actually used is not clear - possibly about 2 tons water per ton ore.

At Yellowknife water is not in short supply at all, the only limitations would be the cost of pumping it and the permit to use it.

JAPANESE TOWER MILL

A Japanese Tower Mill has been installed at the Con Mine for grinding cyclone underflow from the secondary cyclones as a secondary grind.

The Con Mine had historically milled to 75% minus 200#. It is hoped to improve recovery slightly, and to expand throughput by adding the tower mill to grind to 80% minus 200#.

The tower mill was working well generally but had experienced some gearbox trouble. Some of the abrasion resistant flights on the tower mill lifting helix had worn out within a year of its being installed.

Cyanide is added to the tower mill to grind in cyanide.

The mill was certainly silent and compact. It is claimed to be energy efficient and all three factors would be advantageous in the cramped mill building of the Con Mines. The mill was so silent there was some question as to whether it was running at the time of the visit.

The Japanese Tower Mill is supplied in North America by:

Mineral Processing Systems Inc.
211 Consumers Rd., Suite 107
Willowdale Ont.
Canada M2J 4G8

Telex: 06-986946
Telephone: (416) 492-7433
Contact: Gordon A. Griffiths
General Manager

Koppers Mineral Processing Systems Division
Koppers Company Inc.
P. O. Box 312
York, PA 17405
USA

Telephone: (717) 843-8671
Telex: 840446
Contact: Dale M. McLane Product Manager

RANDOL did not have an opportunity to discuss the tower mill with the plant superintendent who was away.

ATARA AIR CANNON MIXERS

The ATARA Air Cannon Mixers had not yet been installed. Three had been purchased together with two more agitators to provide better agitation at a lower energy consumption.

ENERGY

Cominco Ltd. own and operate a hydropower plant not far from Yellowknife, believed to be at Churchill Falls. This provides part of the power required by the Con Mine. Incremental power is likely to be very expensive, hence it is logical to find the Con mill installing energy efficient process equipment. Furthermore, considering space heating costs in winter, the compactness of the Japanese tower mill is an added energy saving feature.

PRECIPITATION

If the arsenic content is over 2% in the 5 tons per day residue from the arsenic plant, then it is found that several problems occur in the gold plant. One of them is difficulty in precipitating gold from solution with zinc.

ENVIRONMENTAL

The Con Mine is regulated by the:

Northwest Territories Water Board
P. O. Box 1500
Yellowknife NWT X1A 2R3

Telephone: (403) 920-8191
Telex: 034-45622
Contact: Glen B. Warner, Chairman

WATER QUALITY

No data was provided on mine, mill tailings or final effluent quality. It is known that the effluent is high in chlorides, containing 2-3% Cl^-/l introduced with the ore that contains pockets of halite.

USE OF $FeSO_4$

In arsenic precipitation using ferric sulfate, Cominco tests showed that vigorous agitation is essential to bring the arsenic in contact with ferric ions before it precipitates as ferric hydroxide. When adding ferrous sulfate there is more time available because the ferrous ions take awhile to oxidize and precipitate as ferric hydroxide, so allowing coprecipitation of arsenic without such drastic agitation needs. Other advantages of ferrous sulfate are its lower price and the much easier handling than ferric sulfate which is highly corrosive.

EFFLUENT LIMITS

The regulated effluent limits for the gold mill and the arsenic plant in their permit valid from June 1, 1980 - May 31, 1986:

	Max. Average for Discharge (ppm)	Maximum Grab sample (ppm)
As_T	0.50	1.00
CN_T	1.50	3.00
CN Available	0.40	0.80
Cu_T	0.30	0.60
Pb_T	0.20	0.40
Ni_T	0.50	1.00
Zn_T	0.50	1.00
Suspended Solids	15.00	30.00
Oil and grease	-	5.00
pH	6.0-9.5	6.0-9.5

Comment: The above apply to the discharge from the tailings pond decant basin at the far end of the tailings pond from the mill, where effluent is discharged via the lake system to Great Slave Lake.

TAILINGS DISPOSAL

Tailings after repulping the filtercake with freshwater are cycloned to make a sand slime split approximately in the ratio 400 tpd slimes : 350 tpd sand.

Sand is pumped underground as a 60% solids slurry using minewater. Slimes are pumped from the cyclone overflow at 25% solids to the tailings dam where they are discharged at the end closest to the mill. Barren bleed is blended back into the slimes pulp as it leaves the plant and before $FeSO_4$ and Na_2S are added to detoxify cyanide and precipitate metals.

The Con Mine tailings dam is a large shallow segmented basin which appears to have originally been a lake. As it has filled up with tailings, a dam wall has been constructed at the downgrade end of the dam.

Because of the long freezing winters tailings solutions are accumulated during the winter months. During 1983/4 there appeared to have been a tailings dam breach which had been repaired and the dam height was being raised using a steel pile curtain.

The large shallow surface area of the tailings dam is believed to result in polishing of solution by natural degradation of residual cyanide in the effluent solution. During winter months the cyanide level and liquid volumes in the tailings increase.

TAILS & EFFLUENT TREATMENT

The tailings solution treatment is carried out in two steps:

1) Ferrous sulfate and sodium sulfide are added at the point of pulp discharge to the tailings dam. At this point the pH is 10.5-11.0.

2) Ferrous sulfate and lime are spread into the tailings pond at the discharge end close to the overflow ahead of the decant as a means of dropping more arsenic as a safety measure after connecting the arsenic plant sewer to the tailings pond.

CONSUMABLES

Cyanide	:	Averages 1000 lbs NaCN/day	
Lime	:	Average 21.3 bags @ 50 lbs/day	= 1065 lbs/day
$FeSO_4$	:	Average 18.4 bags @ 50 lbs/day	= 920 lbs/day
Na_2S	:	Average 3.6 bags @ 50 lbs/day	= 179 lbs/day
Zn dust	:	Average 56.4 lbs/day	
Pb Acetate	:	Average 14.0 lbs/day	
3" steel balls	:	570 lbs/day	
1½" steel balls	:	300 lbs/day	

DISCUSSION

Based on the reagents used and the sequence of their addition it appears that the addition of Na_2S + FeS with the tailings at discharge (pH 10.5-11.0) will react with complexed metal cyanides to precipitate the metals and remove cyanide according to the patent by Walter J. Kuit and Alan R. Babcock assigned to Cominco.

Addition of ferrous sulfate and lime downstream seems to be a step to remove any excess arsenic added with effluents from the arsenic plant.

What is curious about the procedure is that in the Kuit and Babcock patent, pH is adjusted to pH 7.5-8.5 to make the process work. It is not clear how/if pH is adjusted at CON tailings dam or whether this occurs naturally.

ARSENIC RECOVERY PLANT

INTRODUCTION

The arsenic plant is an example of how an environmental liability was to be converted to a profitable byproduct by a simple process. This turned into a larger investment with more process headaches than anticipated. Arsenic has been an emotional issue at Yellowknife despite no confirmation of it ever having harmed anyone.

PROCESS DESIGN

The arsenic recovery process was developed by COMINCO. One person particularly knowledgeable in the process is:

Dr. Lorne Ball
Group Leader - Chemical Metallurgical Research
Cominco Ltd.
Trail, BC

Telephone: (604) 364-4419

CAPITAL COST

Capital cost was budgeted at C$12 million for a 15 stpd As_2O_3 production. The actual plant cost C$14 million.

PLANT STARTUP November 1982

FEED MATERIAL

Arsenic oxide dusts were collected by wet Doyle Impinger scrubbers on the Edwards Roaster gasstream treating arsenical goldbearing sulfide flotation concentrates from the Con Mine from 1938 to 1972. About 30,000 tons of the dusts containing about 85% As_2O_3 and 0.3 oz Au/t was accumulated in the two small open ponds at the Con minesite. The material also contains dust, antimony, lead, iron and some sulfide. The leached arsenic residue contains about 0.69 oz Au/t and 2% As_2O_3.

PLANT CAPACITY

The plant was designed to treat a maximum of 30 tpd feed for about 15 stpd As_2O_3 product. This throughput has not yet been achieved.

MOTIVATION

The arsenic ponds at Con Mine, although small in size, contain a considerable amount of arsenic in a soluble form contained in ponds that are not isolated from groundwater.

Located near the environmentally sensitive Great Slave Lake the arsenic ponds were a cause of concern to both Cominco and the Canadian Government. Something would have to be done to fix the arsenic in these wastes in a permanent and safe manner.

Economic incentives to treat the arsenic pond materials were:

1) Recovery of a salable arsenic product
2) Recovery of an incremental gold raw material
3) Alternative means of disposing of the arsenic and restoring the ponds would require capital and operating expense anyway.

The potential gross value of the arsenic and gold in the arsenic ponds appears roughly to be:

Arsenic	:	30,000 x 85% As_2O_3 x C$800/t	C$20,400,000
Gold	:	30,000 x 0.3 oz Au/t x C$430/t	3,870,000
		TOTAL	C$24,247,000

Assumption: 10% of the solids in the feed to the plant remain insoluble after arsenic has been leached.

PROCESS

The feed material is leached in hot water at 95°C at pH 3-5. Reagents such as H_2O_2 or H_3PO_4 are added to the leach vessel to precipitate impurities such as Sb, Pb, S, Fe etc. which are settled and removed. This is done as a two stage leach each stage followed by decantation of solids.

Supernatant leach liquor from stage 1 leach advances as pregnant liquor to the 4 stage crystallizer circuit. Supernatant solution from the second thickener after leaching the solids a second time advances to become leach liquor to the first stage leach.

The pregnant solution is concentrated in a three stage multi-effect crystallizer to drop coarse arsenic oxide crystals. The crystals are dewatered on a Dorr-Oliver horizontal pan filter and the filtrate pumped to the mother liquor tank for return to the leach tank.

Insoluble residue that did not leach is cooled, thickened and dewatered in a Larox pressure filter before being transported in a cement truck to the gold recovery plant. The crystallized arsenic product is dried in a plate drier and packaged for shipment.

FEED HANDLING

Arsenic sludges are reclaimed from the outdoor pond in the summer months using 3" Ø Toyo pumps. This pump can transport material with up to 60% solids and has worked well in this application. The slurry is boosted by a centrifugal pump which moves the material to one of three indoor storage pits after first screening it to remove trash. The capacity of these impoundments is adequate to store feed for the plant through the frozen months, estimated therefore as 25 weeks x 7 days x 30 tpd = 5200 short tons solids.

Toyo sludge pumps are available from:

Toyo Denki Industrial Company
1-7-10 Norimatsu Yahatanishi-ku
Kitakyushu City
Japan

Toyo Pumps North America Corporation
Esplanade Centre
119-255 West 1st Street
North Vancouver, BC
Canada V7M 3G8

Telephone: (604) 988-7187
Telex: Waterfront 0435-2841

Contact: Richard Binning

There were some initial problems with wood particles clogging of the system and with corrosion of the pump motor seals which allowed the arsenic to get into the motor. The stainless 304 seals were replaced by stainless 316L steel to solve the pump problem.

The building that houses the indoor sludge stockpile is heated just enough to prevent the material from freezing. The necessity for indoor storage has added significantly to the capital cost of the operation.

Seepage from the three indoor sludge storage pits is intercepted and pumped back to the system.

During summer the storage impoundments are decanted and water is returned to the outdoor sludge pond.

LEACHING

Solution returning from the crystallizer and filtrate from the arsenic crystal dewatering step is returned to the mother liquor tank where it is heated to become leach solution at 95°C. The arsenic level in the leach liquor reaches 53g As/l.

H_2O_2 and/or H_3PO_4 are added in the leach tank to precipitate unwanted impurities and apparently to enhance arsenic dissolution.

Solution is heated by heat exchangers which in turn are heated by steam coils.

Arsenic in the leach residue must be reduced to below 2% As or problems are in Merrill-Crowe gold precipitation.

INSOLUBLE RESIDUE

5 - 15 tons per day of leach residue is returned from the arsenic plant to the gold plant at 0.69 oz Au/t. The residue is dewatered in a Larox pressure filter to remove as much soluble arsenic as possible. The cake is repulped to 60% solids for transport to the gold plant in a cement truck. It runs 0.6-1.0 oz Au/t.

ARSENIC PRODUCT

The arsenic is crystallized in large crystals to satisfy market demand. Product quality typically is:

As_2O_3	99.5%	
Sb	0.3%	max
S	0.1%	max
Pb	0.02%	max
Fe	0.016%	max

Large arsenic crystals make it possible to reduce dusting in handling the product.

OPERATING STARTUP PROBLEMS

1. There have been startup problems with the multi-effect crystallizers which have yet to achieve design capacity of 15 stpd As_2O_3.

2. The centrifuge originally installed to dewater the arsenic crystals did not work. It has been replaced by a Dorr-Oliver horizontal pan filter.

3. Seals on the Toyo pump for reclamation of sludges from the pond and from the indoor storage pits were corroded by the arsenic to the extent that arsenic sludge got into the motors. This was overcome by replacing the stainless 304 steel seals with 316L seals.

4. The plant is fitted with stainless steel 304 piping. Some of these lasted 2 weeks before being corroded through by the arsenic solution.

5. The antimony level in the lab tested solutions was reduced by H_2O_2 or H_3PO_4 addition. In the plant however antimony did not get depressed to the same extent.

6. The complexity of the counter current leaching by hot water seems to be easily underestimated.

ENVIRONMENTAL

Arsenic vapor gets into the working atmosphere in the plant. To prevent loss of arsenic to the environment as dust, the plant is completely enclosed which results in a hot, humid working environment.

Any antimony in the feed ends up leaving the plant in the undissolved gold-bearing residue or in the arsenic oxide product.

No water is discharged from the arsenic plant. It is operated as designed on a zero discharge basis, except for a sewer to the tailings pond.

Arsenic rashes are experienced by some workers. In some areas workers were asking for "space suit" type protective clothing, but it is questionable whether these would provide the protection hoped for. It appears that the hot, perspiration prone environment inside space suits might well result in a greater likelihood of arsenic rash than without the space suit.

All personnel are limited to 5 hour shifts in the arsenic plant. Urine samples are taken for analysis in and out of each shift.

No TLV has been decided on yet for arsenic. If the urine analysis level is below 500 micrograms As per liter then it has been decided in the interim that a worker may work in the plant. An arbitrary level of 50 ug As/m^3 air limit in the plant has been set. The plant air is around 20 ug As/m^3except around the arsenic feed pits where it is higher.

Workers are issued with special overalls and boots for working in the arsenic environment. Before leaving the plant they shower in the changehouse and then cross to the other side of it to change back into street clothes.

Con Minesite with Yellowknife in background.

INTRODUCTION

ERGO recovers gold, uranium and pyrite (sulfuric acid) by re-processing 1.6 million tons of slimes per month from the tailings dams left by the previous gold mining operations on the East Rand.

Large amounts of water are used by this undertaking and several items of particular interest from a water management standpoint were identified:

1. Water Saving measures through increased recycling of effluents.

2. High TDS underground minewater used as a major water source for the plant.

3. Gypsum scale problems, monitoring and counter measures.

4. An innovative process for the removal of arsenic and cyanide from existing effluents.

5. TDS levels in the effluents that are relatively high, but still within statutory limits.

6. The possible future need for desalination to reduce TDS levels in these effluents.

7. A new CIL installation for the recovery of additional gold from flotation tailings, that utilizes the last seven out of a total of eleven carbon contacting stages for cyanide removal. The tailings from this plant are pumped to a new disposal dam.

DESCRIPTION OF PROCESS

The ERGO process and plant is described in the attached document made available by the company.

MAJOR WATER SUPPLIES AND USES

ERGO uses the following water supplies.

1. Rand Water Board (Potable) Water - 563m³/hour

In response to water savings measures necessitated by the prevailing drought conditions, ERGO has cut back its Rand Water Board water consumption to essential applications only. This includes, in most cases, the conversion of gland service requirements to process water. Some thought might be given to the use of engineered plastic sleeves to reduce abrasion of pump shafts when this low quality water is employed for gland service. A company that could possibly make useful suggestions is:

Virginia Engineering Services (Pty) Ltd.
P. O. Box 47
VIRGINIA O F S

Contact: Alan Leger

2. Underground Mine Water from Grootvlei Pumping Operations - 1517m³/hour

The neutralized mine water is pumped up from underground by Grootvlei Mines (Pty) Ltd. via the old S A Lands and Exploration Company pumping installation and shaft. It arrives at ERGO at 29°C and is cooled to 21 - 23°C by evaporation sprays in the process water reservoirs. In 1983 a further R60,000 was spent on improving the cooling spray system.

This water is mainly used in the Acid Plant in both the calcine quench tanks requiring a total of 150m³ water/hour and in the Peabody Scrubbers requiring 1650m³ water/hour to scrub calcine dust particles out of the roaster gases prior to drying and conversion to SO_3 for acid production. The calcine solids are removed from the quench and scrub waters in two thickeners.

The thickener overflow at pH 1 is pumped to the Flotation Plant where a 1000m³/hour is used for dilution and acidification of the flotation feed pulp and the balance, 900m³/hour, is sent to a two stage effluent treatment plant fitted with Envirotech

surface aerators. 50m³/hour raffinate and sufficient lime to adjust the pH to 7, are introduced into the first stage. Additional lime is added to the second stage to produce a pH of 8.5.

The overneutralized product (solution and sludge) of the effluent plant is delivered into the flotation tailings thickener distribution box, where it is used for the neutralization of the pH 3.8 flotation tailings. Small amounts of lime are also added to the thickener feed launders for final pH control. This method of neutralizing the excess calcine thickener overflow and flotation tailings has been found to give the most effective use of lime and better pH control. Total lime consumption for this purpose is 2.4 kg/ton of solids in the flotation feed.

Raffinate containing 6,400 ppm iron is added to the effluent plant to boost the overall iron concentration thereby ensuring that sufficient ferric hydroxide is formed by the high pH and vigorous aeration, to co-precipitate the 32 ppm arsenic typically found in the calcine thickener overflow. The arsenic is removed to below 0.5 ppm.

A typical analysis of the underground water as received at ERGO is:

Conductivity		237	mS/m
pH		7.9	
TDS		1939	ppm
Suspended Solids		7	ppm
Total hardness	(as $CaCO_3$)	984	ppm
Sulfates	(as SO_4)	984	ppm
Chlorides		170	ppm
Fluorine		1	ppm
Potassium		9	ppm
Phosphates	(as PO_4)	1	ppm

Out of necessity, ERGO uses more underground water in the Acid Plant than is required to make up the total water losses in the circuit. For this reason, ERGO has to dispose of its excess water by way of effluents at both the Complex and the tailings dam.

3. Water Associated with S A Lands Gold Plant Tailings - 553m³/hour

The S A Lands and Exploration Company currently disposes of its Gold Plant tailings by pumping them into ERGO's tailings thickener distribution box. Some of the water associated with these tailings is recovered in the thickener overflows, while most of the remaining water is decanted from the solids at the ERGO tailings dam.

4. Water Associated with Simmergo Plant Tailings - 292m³/hour

The Simmergo tailings are scheduled shortly to be pumped via a 38 kilometer pipe-line directly to the ERGO tailings dam, where the bulk of the water associated with these tailings will be removed.

WATER BALANCE

A generalized water balance is shown in the attached drawing. The balance includes the new CIL Plant and the scheduled pumping of Simmergo tailings to the ERGO tailings dam. Seepage and evaporation losses are also given.

EFFLUENTS

1. Complex Effluents

The clear water reservoir is the collection point for the overflows from the four 138m tailings thickeners plus 504m³/hour of the ERGO tailings dam return water. A total of 2 580m³/hour of water from this reservoir is pumped via high pressure Allis Chalmers pumps to the reclamation sites for slimes recovery. The excess water (540m³/hour) is allowed to overflow from the reservoir, gravitating to a primary and secondary settling pond system.

The primary system consists of two parallel ponds. When one becomes full of settled sludge, the flow is switched to the second so that the sludges can be removed by hosing from the first.

The second system is made up of two large reed-filled ponds which remove the remaining suspended solids to below 25ppm. The reeds and associated ecosystems are also known to reduce sulphate levels.

The total overflow from the second settling pond system was until July 1983 discharged into the Rietspruit with the Vaal River as the ultimate destination. Now approximately 40% of this effluent is recycled to the process water reservoirs at the ERGO complex.

2. Tailings Dam Effluent

The underflow from the four flotation tailings thickeners is pumped to the tailings dam and discharged via a ringmain with cyclones around the periphery of the 791 hectare (+ 1750 acres) dam. The cyclone underflows are used for wall building and the overflows migrate to the central area, forming gently sloping beaches. The walls of the tailings dam are constructed with a 1:3 slope.

The water run-off collects in a central pond from where it is removed by a mobile decant system consisting of a barge fitted with large Flygt pumps that deliver via flexible hoses into Allis Chalmers pumps mounted on a moveable land-based platform. This system pumps the decanted water to activated carbon columns for soluble gold adsorption. The water then gravitates to a decant station and thence via a cement enclosed pipe under the dam wall into the toe trench which runs parallel to the walls around the outer periphery of the dam. All seepage gathered by the toe drain network from the dam walls also enters this trench.

The lowest point of the toe trench acts as a collection point from which an average of 938m^3/hour of tailings dam water is returned via four 200HP APE Sangus multistage vertical spindle pumps to the ERGO complex, where 434m^3/hour enters the process water reservoirs and the balance of 504m^3/hour is delivered to the clear water reservoirs (see Section 1 above). The actual amount of return water pumped is controlled by the number of APE Sangus pumps on line.

Excess tailings dam water (697m^3/hour) is discharged as an effluent from the same toe trench collection point, eventually joining the Complex effluent in the Rietspruit.

Immediately the new R56 million Carbon in Leach (CIL) Plant comes on line, ERGO's tailings will be pumped to a new dam currently under construction adjacent to the existing tailings dam site, at a cost of R31 million. The latter amount is being funded as part of the Daggafontein slimes dam treatment project, which also provides for the future retreatment of the existing tailings dam in the ERGO CIL Plant.

Water run-off from the new tailings dam will be handled in six collection area each with its own mobile decant system. These decants will deliver into a central holding pond, from where the water will be pumped initially into the existing tailings dam for disposal via the present pumping systems and carbon columns. Eventually the new dam will have its own decant station and return water pumps.

ERGO TAILINGS DAM

MOBILE DECANT SYSTEM - ORIGINAL CONFIGURATION

PROFILE OF WALL AREA

3. Effluent Analysis

The composition of the Complex and tailings dam effluents are as follows:

		Complex	Tailings Dam
Total effluent generated	m^3/h	583	1635
Amount recycled	m^3/h	220	938
Amount discharges	m^3/h	363	697
Conductivity	mS/m	363	375
pH		6.8	7.3
TDS	ppm	3408	3581
Suspended Solids	ppm	20	45
Total Hardness (as $CaCO_3$)	ppm	2168	2271
Sulfates (as SO_4)	ppm	1993	2101
Chlorides	ppm	154	162
Fluorine	ppm	1	1
Sodium	ppm	171	187
Potassium	ppm	40	49
Phosphates (as PO_4)	ppm	1	1
Cyanide (as CN)	ppm	0.5	0.5

4. Calcine Dam Effluent

$50m^3$/hour raffinate is added to the Gold Plant residue pachuca containing repulped calcine which has been leached at pH 10.5 with cyanide and filtered for pregnant gold solution recovery. The raffinate drops the pH of the calcine residue to $^+$ 7.5. The low pH and the air agitation in the pachuca destroy most of the free cyanide and the balance is converted by the high iron concentration in the raffinate to stable iron-cyanide complexes.

The raffinate-treated Gold Plant residue was until recently pumped to a separate calcine tailings dam, with the decanted water as effluent being injected into the tailings dam feed pipe-lines. Currently the cyanide-free calcine residue is deposited directly with the flotation tailings on the ERGO tailings dam.

CAUSES OF TDS BUILD-UP IN THE ERGO WATER CIRCUIT

Salts are introduced into the ERGO water circuit from the following sources:

1. Soluble oxidation products of pyrite in slimes feed material add Fe^{2+}, Fe^{3+}, $SO_4^{=}$, H^+ and undoubtedly dissolved Al^{3+} and silica.

2. Reagents added for pH control are by far the greatest contributers to TDS build-up. These are:

   a. Calcine thickener overflow ($^{+}$ 1.5g/l sulphuric acid) and concentrated sulphuric acid used for dilution and acidification (pH 3.5 - 4.0) of the incoming pulp prior to pyrite/gold/uranium flotation;

   b. Lime addition for neutralizing the acidic flotation tailings and the excess calcine thickener overflow solution, and for protective alkalinity during cyanide leaching of the calcine.

3. 100m^3/hour of raffinate is generated in the Uranium Plant, and can contain from 30,000 to 40,000 ppm TDS. Half of the raffinate (50m^3/hour) is used to assist in co-precipitating arsenic from the excess calcine thickener overflow in the effluent treatment plant and the balance, for cyanide destruction/complexing in the Gold Pant residue. Some of the salts associated with the raffinate and other high TDS solutions obviously precipitate out of solution when contacted with lime to pH 7 and above.

CALCIUM SULPHATE SCALE PROBLEMS AND COUNTER MEASURES

ERGO's water circuit is saturated with calcium sulphate. This has led to severe scaling problems in the past. When it first occurred in the major pipe-lines, high pressure water cleaning was used on the slurry lines because the scaling was relatively soft, but this proved ineffective on the monitor water lines where the scale formation was extremely hard. The only cost effective method of removal in this case proved to be blasting using long lengths of detonating fuse on the outside of the pipe, covered by a mud pack. This method could not be repeated because of partial pipe deformation.

By 1980 antiscalant reagents were being used to prevent calcium sulphate precipitation, the first reagent being Antiprex supplied by Allied Colloids S A (Pty) Ltd.

Allied Colloids (S A) (Pty) Ltd.
P. O. Box 48775
Roosevelt Park 2129

Telephone: 782-5335
Telex: 4-24410 SA
Contact: Robert M. Page

The reagent in use at the time of the visit was Anikem 4393 supplied by Anikem (Pty) Ltd, a South African subsidiary of Nalco.

Anikem (Pty) Ltd.
P. O. Box 67817
Bryanston 2021
Telephone: (011) 706-6106
Telex: 422256 SA
Contact: Merwyn S. C. Wilson

The total dosage rate was 6g/ton of feed to the Flotation Plant, added to the monitor water circuit.

Other antiscalants tested include CL4000 supplied by Floccotan (Pty) Ltd (for address see below) and PC 40 from Ferste Chemicals (Pty) Ltd.

Ferste Chemicals (Pty) Ltd.
P. O. Box 41109
Craighall 2020
South Africa

Telephone: (011) 787-8857
Contact: Stuart Ferguson

ERGO is currently developing a modified NACE method that will give a reliable performance comparison between the different antiscalant products and allow addition rate optimization.

Coupons are suspended at various points in the ERGI water circuit to monitor scale build-up on a monthly basis and pipe-lines are opened for regular inspections. Tests are being conducted on a dynamic scale-monitoring device developed by Calgon and available in South Africa from:

Floccotan (Pty) Ltd.
P. O. Box 4578
Randburg 2125
South Africa

Telephone: (011) 789-3823
Telex: 4-26994
Contact: John Hallows

The Dynamic Scale Monitor device is also available from:

Calgon Corp.
P. O. Box 1346
Pittsburgh, PA 15230

Telephone: (412) 777-8000
Contact: Frank Daniher

The monitor water and slurry pipe-lines, plus certain critical lines in the plants are now 'pigged' on a regular basis with plastic pigs to clean out any scale build-up that occurs. The flotation tailings thickeners and the effluent treatment plant are also taken off line on a scheduled basis for descaling.

There has not been much of a scale problem in the tailings dam return water line even though the TDS levels are usually in excess of 3,500 ppm, with 2,059 ppm sulphates which is at or over saturation.

WATER SAVINGS THROUGH RECYCLING OF EFFLUENTS

In the past, Rand Water Board (RWB) water was used to make up any shortfalls in underground water from Grootvlei pumping operations, required by the Acid Plant for calcine quenching and dust scrubbing. Since July 1983, recirculation of a portion of ERGO's effluents into the process water reservoir has reduced RWB water make-up to emergency situations only, resulting in a 18% drop in consumption.

The recycled effluents have also compensated for the underground water required to replace RWB water in other applications.

EFFECT OF RECYCLING ON EFFLUENTS

No noticeable effect on metallurgical performance, scale build-up or effluent quality has been encountered with the increased recycling of effluents to date. The effects of further increases in effluent recycling are unknown at this stage, but more precipitation and an increase in the level of soluble salts could be expected.

SALT BALANCE MODELLING

The ERGO complex plant represents an excellent example where a good salt balance model could be helpful in predicting the cost and effect of various alternative strategies for water management. Names of a few consultants who are learning how to model salt balances are provided in Chapter 10.

ENVIRONMENTAL ASPECTS

The slimes dams left over from the previous gold/uranium mining operations that contain pyrite, are expected to be AMD generators and can lead to seepage of AMD to contaminate aquifiers. ERGO by reclaiming these dams and removing pyrite by flotation, is reducing the long term acid generating capacity of the slimes and thereby helping in the long term reduction of TDS build-up in the local regional water supply.

ERGO's effluents also meet the current quality standards set by the Department of Environment affairs.

The ERGO pollution officer follows the potential pollution route daily, sampling all effluents and the local stream for laboratory analysis. Various additional control points in the Complex are also sampled. Principle items of interest in the daily analysis are suspended solids, cyanide, arsenic and pH.

POSSIBLE FUTURE NEEDS FOR DESALINATION

Considering the scaling nature of the recycled solutions and effluents from ERGO, any processes considered for desalination of effluents would have to take this into account. Two approaches might be considered - one is to treat all the effluent to the conductivity level of 250 mS/m, i.e., about 1900 ppm TDS or to treat half the flow all the way and blend it back. Seeded reverse osmosis (SRO) is the only method that would drop the TDS level while avoiding serious membrane fouling problems.

ERGO is currently running a SRO pilot plant in conjunction with RCCI.

A rough estimate of the capital costs for a full scale SRO plant to treat ERGO's effluents would be R12 - 18 million, with an operating cost in order of R0.45/m^3.

Other area being considered for improving effluent quality include sulphate level reduction by bacteria in either natural or controlled environments.

An aerial view of the complete treatment plant

How it all began

For more than 20 years Anglo American had been building up valuable experience in the treatment of gold plant tailings, both from dumps stockpiled for their uranium content, and through the recovery of pyrite for sulphuric acid manufacture. The improvement in the gold price and the increased demand for sulphuric acid regenerated enthusiasm for a major independent slimes reclamation project. About 1 000 test holes were drilled in several slimes dams on the East Rand and the results were sufficiently interesting to justify a full scale testing programme.

In the meantime, scientists at the Anglo American Research Laboratories had developed a flotation technique to produce a concentrate of three per cent of the mass of the slimes which contain sufficient gold and uranium to enable a conventional extraction process to be applied.

A pilot flotation plant with a capacity of one ton an hour was erected in 1974 and results confirmed the findings of the laboratory test work. Feasibility studies indicated that flotation would have to be conducted on a very large scale indeed if it were to be viable and the plant would need to treat a minimum of one million tons of slime a month. This posed several crucial questions. For example, what was the best method of transporting the material for treatment? Should there be a very large single flotation plant or three separate flotation plants established closer to the slimes dams destined for treatment? Various means of transportation, including road and rail, were examined and it was eventually concluded that the most economic method was to pump the slimes in slurry form by pipeline to a central processing site. A subsequent investigation carried out by the Council for Scientific and Industrial Research confirmed Anglo American's own conclusions. The CSIR's report also formed the basis of the engineering design of the pipelines and the pumping systems. Test work undertaken at the Group's Vaal Reefs gold mine showed that by 'hosing' slimes with high pressure water cannons an acceptable slurry could be obtained which could then be pumped through large diameter pipes to the central treatment plant complex.

Financing arrangements

In 1975 the Anglo American Corporation Group began providing the main finance for Ergo's expenditure, through a series of interest free loans. By June 30, 1977 these loans totalled about R52 million. The following month Ergo made an offer of 16 million shares at R3,50 a share, of which 12 250 000 shares were firm subscriptions by certain companies and financial institutions. When the offer closed on July 29, applications totalling R286 million had been received, a record for a South African share issue, and the 3 750 000 shares offered to the public were subscribed eighteen-and-a-half times. Since the inception of the company, the net proceeds available from the issue of equity capital amounted to R114,8 million with the balance of funds for Ergo's capital expenditure being provided by revolving credit facilities and short-term borrowings. In November 1977 Ergo received the Rand Daily Mail's Business Achievement Award in recognition of its pioneering technical accomplishments and its outstanding contribution to the development of the South African economy.

Tailings disposal and return water pipelines with acid plant and storage tanks in the background

The process

Dam reclaiming

Specially built remote controlled, and hydraulically operated water cannons direct jets of water under high pressure – 2.5 MPa – at the dam walls. A battery of three cannons 'monitor' each of the three dams being worked and every hour the combined cannons use 2 500 cubic metres of water to slurry 2 100 tons of solids which are gravity-fed to the adjacent pumping station. After screening the slurry is pumped through large pipes to the flotation plant at the Ergo complex some 10 or more kilometres away. Three slimes dams are monitored simultaneously, with two main pipes servicing each dam: one pipe carrying water for the monitoring guns and the other carrying the slurry.

Flotation plant

The slurry is processed in the flotation plant to recover gold, uranium and sulphur in the form of a pyrite concentrate. Treatment is in three separate streams each of

Left: The pachuca area of the flotation plant
Right: Processing of the slurry through the flotation plant
Bottom: A cyclone in operation at the tailings dam

The uranium plant with the repulper in the foreground
Bottom: The 500 tons a day acid plant

approximately 500 000 tons a month, to accommodate any difference in metallurgical characteristics that may exist in the respective dams. The slurry is diluted before sulphuric acid and various chemical reagents are added, to prepare the pulp for froth flotation. The low value mineral content of the pulp requires large tonnages to be processed to ensure profitable recovery of these minerals. By passing through a series of flotation cells the pulp yields valuable minerals which are floated in a froth from the waste, and the pyrite is then passed through two thickeners before delivery to the uranium plant. The process is supervised from the main control room.

Tailings disposal

In the meantime, the residual slurry from the flotation plant cells is delivered to three 138 metre diameter thickeners before being pumped to a tailings dam far removed from built-up areas. Here the solids in the slurry are separated from the water and remain at the tailings dam site, while most of the water is pumped back to the Ergo complex for re-use by the monitors at the slimes dam reclamation sites. Additional water is obtained from the underground workings at SA Land gold mine or from the Rand Water Board. The pollution-free tailings will be systematically dumped over the years into a 750 hectare disposal area, and research into suitable vegetation cover is currently being undertaken.

Uranium plant

The pyrite concentrate is pumped as a pulp from the flotation plant to the uranium plant, where it is heated by steam and sulphuric acid is added to dissolve the uranium oxide. The pregnant solution (containing uranium) is removed from the pyrite by rotary filters and the pyrite residue is pumped as a pulp to the sulphuric acid plant. Any fine solids remaining in the solution are removed by settling tanks and filters in order to prevent problems in the solvent extraction plant. The solution is then mixed with a solvent consisting of a special reagent (amine) dissolved in paraffin. This absorbs the uranium into the solvent leaving behind all the impurities in a solution which is returned to the flotation plant. After a further purification stage of the solvent, the chemical conditions are changed forcing the uranium out of the paraffin into a water solution. The solvent is then re-used for the uranium extraction step. The final product called ADU (Ammonium Di Uranate) is then precipitated as a solid by adding ammonia to the solution. The ADU is despatched in slurry form by road tanker to Nuclear Fuels Corporation of South Africa.

Sulphuric acid plant

The leached pyrite concentrate is pumped to the sulphuric acid plant from the uranium plant. It is then fed into the roasters where in the presence of air the sulphur burns to form sulphur dioxide, and a residue called calcine. The sulphur dioxide gas is cleaned, cooled and dried and then reacts with oxygen in the presence of a catalyst to form sulphur trioxide, which is dissolved in strong (99%) sulphuric acid, and its concentration is maintained at this level by the addition of water. The hot calcine residue, containing gold, is discharged from the roaster, cooled and after mixing with water, pumped to a calcine thickener. The overflow is reclaimed and pumped to the flotation plant, and the calcine underflow is sent to the gold plant.

INTRODUCTION

The ERPM Mine is an underground drainage point for the mines on the east Rand from which water is pumped to the surface at 64,600 m^3/d (average).

Since 1970 ERPM has operated a large high density sludge process, designed under license from the Bethlehem Steel Corp., which does an excellent job of removing iron and adjusting pH while yielding manageable volumes of sludge.

During the 1982-4 drought an immense amount of attention has focused on South Africa's water supply situation and it has been concluded that non-precipitatable dissolved solids in the regional water supply will continue to rise unless something is done to limit the amounts that flow into the Vaal Dam with drainage from the area. A major study for the Water Research Commission by a local firm of civil engineers, Stewart Sviridon & Oliver, concluded that about one third of the point source TDS in effluents was derived from mining and milling in only 12% of the volume of effluent. These point sources accounted for 129,000 tons per year of dissolved solids in 43 million m^3/year of effluent with an average TDS of 3000 ppm.

Based on the above data, the Department of the Environment has started to exert government pressure on mines that discharge effluent into the Vaal catchment, to find ways to reduce the dissolved solids level of their effluents. In a joint test program funded by the Chamber of Mines of South Africa, the Water Research Commission and Rand Mines Ltd., several desalination processes have been evaluated and tested at ERPM. These tests were still in pilot stages during the RANDOL visit to South Africa in March, 1984.

The results of the pilot tests were considered confidential at that stage, however several observations could be made. Details of the HDS treatment were assembled from several published sources including VAN STADEN (1979).

WATER VOLUME

ERPM used to pump 6,800 m^3/d to the surface which was neutralized conventionally to achieve about 4 g/l solids in the underflow density. When a number of mines in an area measuring 40 Km E-W and 10 Km N-S stopped operating, the underground flow of water to ERPM increased to about 50,000 m^3/d. ERPM collected this water at the 29 level by plugging shafts etc. preventing it from reaching lower workings. Th s enabled the water to be pumped to the surface by single stage pumping.

UNDERGROUND NEUTRALIZATION

Underground neutralization of acid mine drainage collected in the mineworkings is necessary to prevent excessive corrosion of equipment and to meet legal requirements prior to disposal. This application was said to be a major part of the total lime consumption in the South African Mining Industry. Acid mine drainage is neutralized to pH5-5.5 underground before being pumped to the surface.

HIGH DENSITY SLUDGE PROCESS

After neutralization to pH 5-5.5 underground, the water is pumped to the surface where it must be aerated to oxidize ferrous ions to ferric. The treated water flows to a settler in the conventional process, to settle $Fe(OH)_3$.

In the conventional process, the 45,000 m^3/d water with 5000 precipitatable solids would generate 250 tpd solids. At a sludge density of only 4% solids, this would generate 6250 m^3d sludge. The logical way to dispose of this would be by mixing it with the gold plant tailings pulp for disposal to the tailings dam. The maximum that could be disposed of in this way was 2727 m^3/d.

The HDS process, developed by Bethlehem Steel, proved to be a practical solution to the problem by producing a high density sludge with a correspondingly lower volume to be disposed of.

An important aspect of the HDS process is the recirculation of a large percentage of the sludge which is mixed with lime and then mixed back into new feed water. Precipitation of metals takes place in layers which yield large particles in a dense sludge. One aspect of concern initially was whether the preneutralization of water underground to pH 5-5.5 would interfere with the HDS process - it did not.

UNDERGROUND NEUTRALIZATION

Four stainless steel pipes feed water from the plug in the shaft to a common mixing chamber. Lime slurry is added by gravity to pre-neutralize the water to pH5-5.5. Very little iron is precipitated at this stage. Four pumps move the preneutralized water from

H.D.S. FLOW DIAGRAM

CONVENTIONAL LIME NEUTRALISATION METHOD

A = NEUTRALISATION / AERATION TANK
B = SETTLING TANK

Source: VAN STADEN (1979)

the mixing chamber via two 356 mm Ø mild steel pipes to the surface. Each pump is driven by a 4000 KW motor and can pump 17,000 m^3/d against the 1050 m^3 head. In each case two pumps serve one of the two vertical lines.

HDS Plant Description

On the surface two mixing tanks A and four aeration tanks B were designed to treat a total flow of 90,000 m^3/d providing a 100% standby capacity.

Two clarifiers C were designed from settling curve data. Considerable flow flexibility is built into the design.

Ground, unslaked lime (-2 mm) is supplied by the Northern Lime Co. Ltd. from a plant at Lime Acres, Cape Province. Lime is delivered in rail tankcars and is pneumatically off-loaded into seven storage and one feed silo. Each silo has a capacity of 200 t.

Lime is slaked in two Omega slakers installed in parallel to give a milk of lime with SG=1.05 equivalent to 5 g CaO per 100 g suspension. The milk of lime is passed through a settler to eliminate coarse particles which may be carried over from the slakers and which would damage the multi-stage pumps underground. Settler overflow is piped underground for pre-neutralization.

The lime settler underflow is pumped to the HDS plant. About 10% of the total lime consumption is used for pre-neutralization underground, the remainder being consumed in the HDS plant.

Water level behind the plug in the shaft is monitored by measuring the water pressure and the pumping rate is varied accordingly.

HDS PLANT PERFORMANCE

According to VAN STADEN (1979) sludge densities as high as 50g solids per 100 ml are readily obtainable. By 1979 the plant had operated at an average rate of 34,000 m^3/d, the rate being determined by the amount of water that needed to be pumped from underground.

WATER QUALITY

	Underground Minewater	HDS Product	HDS Sludge
pH	3.6	7.3	
Fe^{2+}	650	Nil ppm	
Fe^{3+}	30	Nil ppm	
TDS	7,500	5,600 ppm	
Solids	(1) 1,650	(2) 15 ppm	Up to 50g/100ml

(1) Precipitable Solids
(2) Suspended Solids

CAPITAL COST (1975 data)

Surface facilities	R3.2 million
Underground	R1.9 million
Plug in Shaft	R0.5 million
Total	R5.6 million

Additional discussion of the HDS plant at ERPM is provided in the chapter on Acid Mine Drainage Treatment. Until March 24, 1984 Rand Mines was bound by a secrecy agreement with Bethlehem Steel Corp.

More information on the ERPM HDS installation could now be requested via Mr. Johann Wagner at Rand Mines.

More information on the application of HDS for which there have been further more recent improvements can be obtained from:

Bethlehem International Engineering Corp.
Bethlehem, PA 18106

Contact: Jim Forand, Vice President
Stewart T. Herman

LIME CONSUMPTION

VAN STADEN (1979) showed the following curve of lime consumption in Kg lime per m^3 of underground water versus pH to which the water is neutralized which shows that lime requirement to bring the AMD from pH 3.0 to 5.5 for 45,000 m^3/d is 19 tons/d CaO compared with 89 t to bring the pH from 3.0 to 7.5.

Consideration could be given to testing a pre-aeration step of the partially neutralized water pumped from underground to remove CO_2 before adding more lime in the surface

Source: VAN STADEN (1979)

HDS plant, which could possibly result in a lime savings at ERPM, depending on the level of bicarbonate in the water pumped from underground.

DESALINATION TEST PROGRAM

One of the difficulties in desalinating water with high gypsum levels in solution is that as water is recovered, the levels of TDS in the concentrate build up until gypsum and other species precipitate and foul the membrane or evaporating surface, depending on the desalination process employed.

At the Hercules shaft of ERPM a pilot facility was established to develop and test several desalination approaches including Electrodialysis Reversal (EDR) and Seeded Slurry Reverse Osmosis (SRO).

At ERPM an EDR unit and an SRO unit are installed side by side. The EDR plant is compact, but there is a string of pretreatment processing steps ahead of it that are far from compact.

The SRO test system is very compact and requires no pretreatment steps.

SRO is without question a major technology breakthrough in desalination of brackish water - mainly because of its simplicity.

Comparative data for the two desalination systems will ultimately be published either by the Water Research Commission or by the South African Chamber of Mines.

EDR Test Plant

The EDR test unit with pretreatment was an IONICS unit installed by their South African representative:

Process Sytems (Pty) Ltd.
P. O. Box 10142
Johannesburg 2000

Telephone: (011) 802-4230
Contacts: Ralph Jones, Managing Director

Concentration of gypsum that can be tolerated in the reject from EDR is around 2 times saturation, e.g. around 4000 ppm. EDR vendors claim they can operate to 3½ times saturation levels but this must still be demonstrated as routinely applicable for general applications.

SEEDED SLURRY REVERSE OSMOSIS
TEST ARRANGEMENT

SRO Test Plant

The Seeded Slurry Reverse Osmosis plant was installed by RCCI:

Resources Conservation Company International
P. O. Box 47041
Parklands 2121
Telephone: (011) 788-5070

The SRO plant was designed to recover 5 m^3 desalinated water per day and to achieve a 95% recovery from gypsum bearing feedwater without any pretreatment. The R. O. module was installed in the arrangement illustrated below to allow for recycle of concentrate. The pilot unit was a single stage R. O. demonstration test.

A flow diagram for a conceptual 10,000 m^3/d seeded slurry R. O. system achieving 95% recovery is also shown below.

The seeded slurry R. O. system uses tubular R. O. modules. Currently these are available in units that yield 1 m^3/d of product. Consequently for a plant treating 10,000 m^3/d of feedwater, 10,000 R. O. modules would be required.

The R. O. modules installed in the test plant were operating at 4000 kPa or 600 psi.

By employing a seeded slurry recycle concept, the applicability and water quality conditions have been shown to be dramatically extended, which allows for a greatly improved operating range. For example:

Operating Limits for R. O. Modules

Composition of Concentrate	Conventional R. O.	Seeded Slurry	
		Feed	Conc.
Mn	0.1 ppm max	8.4	69 ppm
Fe	0.1 ppm max	6.4	100 ppm
Al	low	280	
Heavy Metals	very low for metals that precipitate e.g. Co, Ni, Sr, Ba		
Sr	very low	40	
Ni	very low	8.0	
Co	very low	2.0	
Silica	160 ppm in reject	No limit	
$CaSO_4$ in reject	1.5-2 times solubility (around 3000 ppm)	No limit	

An interesting set of data was obtained for one application of SRO. It is believed that the data reflects acid mine drainage water treatment by SRO in a situation analagous to ERPM.

DISCUSSION SRO

1. Seeded slurry R. O. as demonstrated by RCC represents a major breakthrough in desalination technology in that membrane fouling is avoided even when recovery is increased to a point where the concentration levels of species in the reject rise to many times saturation which would result in fouling in the conventional application of R. O.

2. Slurry seed is kept in the dihydrate gypsum form for recycling. This is controlled by temperature.

3. A second major advantage of seeded slurry R. O. is that the compact concentrate slurry has a high solids content, i.e., it is compact and less costly to dispose of safely. One way would be to take the SRO reject and recover more water by evaporation resulting in a dry solid waste for disposal. Another would be to mix the reject with a pozzolin to make a pozzolinic dry waste for landfill disposal. Typical pozzolins would be cement, or power plant flyash.

4. In the recycle flow the concentration of calcium reaches about 440 ppm which is not much more than the level of 330 ppm Ca in the feed solution. This is because calcium is removed from solution by the seed crystals.

5. Silica and alumina levels are also effectively controlled by the seed slurry. A typical slurry seed contains 5% SiO_2. Levels of trace elements; e.g., Co, Ni, Zn, etc. are all very effectively reduced as well in the permeate.

6. Because the seed slurry contains solids, it would be expected that there could be abrasion damage to the membrane surfaces. This does not, however, appear to occur.

7. Abrasion of pump impellers etc. could be expected but has not been apparent. In the ERPM test unit, however, some abrasion of the choke valve at the end of the pressure system is believed to have occurred. In a full scale system a different pressure maintaining system would be used: e.g., an orifice plate. It is not known to what extent abrasion will be a problem here.

8. It is expected and hoped that the ERPM tests will proceed using larger scale plants and that their data and experience will be released to industry for general use.

INTRODUCTION

Cambrai Mining Company has attempted to recover gold from an old tailings dump from a former operation that recovered gold in a sulfide flotation concentrate.

Based on promising laboratory tests (presumably using tapwater from Harare) a CIP plant was installed. Results have been extremely disappointing. Although a reasonable percentage of the gold could be cyanide leached, recovery by carbon adsorption has been very poor (25-60%).

This description of results from the plant and in various laboratory experiments shows the following:

1) The complex nature of the gold leaching and CIP adsorption problems. When a process does not perform well, finding the reasons means considering a very wide range of parameters.

2) Water quality effects either because of the quality of available water or because of oxidation products in the sulfide containing feed material appear to be adversely affecting gold adsorption onto activated carbon.

3) The need to test a CIP process on pilot scale using the same water and conditions as planned for commercial scale is indicated.

LOCATION At Gadzema 112 kilometers south of Harare, 12 kilometers west of Harare

RESERVES AND GRADE 928,000 tons of tailings overall
528,000 tons have a grade of 1.4 g Au/t
400,000 tons at a grade of 0.7 g Au/t

RECOVERY Laboratory tests showed that 80% of the 1.4 g in the 528,000 ton section of dump could be cyanide leached in 5.5 hours.

NATURE OF MATERIAL

The Giant tailings have an average SG of 3.1 (dry) and the material contains up to 30% pyrrhotite. Sizing is

4%	+	450 microns
66%	-	450 microns + 44 microns
30%	-	40 microns

PROCESS DESCRIPTION

The dump surface is cemented and has to be ripped and dozed prior to hydraulicing with home-made monitor pumps. The dump material is very acid and the pH of water source being 7, NaOH is added to the main reservoir to raise the pH of water used for hydraulicing to 10.

From a water management standpoint an interesting method of controlling pulp density is employed. This is done by changing the number of monitors in operation at any one time (More monitors reduce pulp density) and by changing the aperture of the water cannon nozzles (these are glass bottle necks). Changing nozzle sizes makes it possible to change water volume and pressures. 1 to 3 water cannons operate at any one time delivering 24 - 30 m^3 water per hour.

The pulp is run along launders, puddled by mechanical puddlers to break clods and then screened over a polyurethane sievebend to remove oversize grass and woodchips.

The minus 450 micron material passes through the sievebend and is discharged into the first 130 m^3 pre-aeration/conditioning tank into which 450 m^3/h air is sparged at 0.6 bars. pH is maintained at 9.5 by lime addition which requires about 10 Kg per ton feed. Pulp in the tank is agitated by a Flygt SR 4500 submersible mixer.

Pulp flows by gravity to the next 130 m^3 leach tank which is also agitated by a Flygt mixer. Cyanide as $Ca(CN)_2$ is added at the rate of 1.5 Kg/t of dry solids to maintain a cyanide strength of 0.03% - 0.04% in solution. Pulp is pumped by Warman rubber lined pump to the first of three 30 m^3 CIP adsorption tanks which are mechanically agitated and 6 x 8 m^3 air agitated CIP tanks and finally over a sievebend to scavenge abraded carbon particles before being pumped to tailings.

Carbon is loaded to 1200-4450 g Au/t depending on carbon fouling. Loaded carbon is acid washed in hot 5% HCl solution for 10-15 minutes to get rid of sulfates and carbonates prior to elution, then tabled to remove coarse grit and to rinse acid, before being placed in perforated containers to drain prior to elution.

1,250 Kg carbon is eluted at a time in a 2500 l mild steel vessel with 3% NaCN, 2% NaOH and 15% ethanol eluant at 65°C pumped via the bottom of the elution column. Pregnant eluate overflows to the electrowinning cell where gold and silver are recovered allowing for 80% recovery per pass. Eluant solution is pumped at 500 l/hour to give a bed volume every 3.5 hours through the carbon. After 60 hours the solution head value drops from 155 g Au/t to 8 g Au/t at which point a further 10% ethanol is added to the eluate which strips a further 200 g Au/t from the carbon over another 60 hours. 1,250 Kg of carbon are eluted in 5 days reducing gold loading from 1200 g to 60-150 g Au/t.

Eluate flows by gravity at 250 l/h through two rows of three plastic electrowinning cells in parallel. Cells are 250 mm wide, 600 mm long and 100 mm deep. 500 g wire wool is layered loosely onto a stainless steel sheet which serves as the cathode. The steel wool cathode is separated from the 3 mm thick stainless steel anode by a 3 mm thick plastic sheet insulator. Current is maintained at 4 V and 20 amps per cell. Steel wool cathodes are treated with 33% HCl then water washed to get rid of iron solution, oven dried, fluxed and smelted.

PROBLEMS ENCOUNTERED

1) The high pyrrhotite content consumes large amounts of oxygen.

2) Fouling of the carbon by sulfates, carbonates and clays seems to inhibit gold adsorption on the carbon.

3) Gold losses to CIP tails increased steadily from 0.15 to 0.4 g Au/t gold in tailings, at which point the CIP operation was suspended.

WATER QUALITY CONSIDERATIONS

Several factors could cause the metallurgical problems experienced:

1. The tailings dump material contains up to 30% pyrrhotite. A typical sample of dump assayed as follows:

Sb	0.14%
Pb	0.04%
As	0.19%
Bi	0.01%

Ni	0.04%
Cu	0.04%
Zn	0.05%
Au	1.6 g/t
Ag	1.8 g/t

The dump also contains weathered mica which is high in soluble magnesium.

2. During aeration of the pulp considerable amounts of calcium and magnesium go into solution. RANDOL questions whether a one-stage pre-aeration tank will be adequate expecially when installed on a flow through overflow basis. Short circuiting will let enough unreacted pyrrhotite through to cause metallurgical problems. These would be expected to inhibit cyanide leaching of gold to consume excessive amounts of cyanide. It is therefore surprising that 0.03-0.04% KCN can be maintained by addition of only 1.5 Kg KCN/t (added as $Ca(CN)_2$), one would have expected a higher cyanide consumption if there was a significant level of pyrrhotite in the feed. Even if all the pyrrhotite was oxidized to sulfate and ferric ions, cyanide would be tied up as ferric cyanate complex.

3. When loaded carbon is acid washed, it fizzes. This indicates that at least some of the scale on the carbon is carbonate. Where does this carbonate come from? Possibilities are :

   - $CO_3^{=}$ could be introduced as HCO_3^- in the water used which is drawn from an old mineshaft, at pH 7.0.

   - The sulfide-rich tailings contain nutrients for bacteria and clearly there is bacterial oxidation of sulfides taking place in the dump. It is possible that CO_2 is generated as a byproduct which is absorbed into moisture in the tailings material. Carbon source could also be flotation reagent degradation products or sewage dumped with the tailings when they were first laid down.

4. Water analysis for the Giant Mine Shaft water is compared with that for the Sherwood Starn project. The Sherwood Starn operation had no difficulty loading gold onto carbon, yet the Giant project experienced very poor loading.

		Giant Mineshaft Water	Sherwood Starn Water	Giant Pulp Solution
Total Hardness	(as $CaCO_3$)	1872	1740	6000
Calcium	(as $CaCO_3$)	486	792	2080
Magnesium	(as $CaCO_3$)	1386	-	3920
P Alkalinity	(as $CaCO_3$)	0	0	0
M Alkalinity	(as $CaCO_3$)	364	426	48
Chloride as Cl^-		24.5	22.5	34.0
TDS		2050	1900	7000
pH		7.1	7.5	7.7
Fe (ppm)		Nil	1.6	-
Silica		26.1	28.7	1.25

From the above analyses it is clear that a large amount of calcium and magnesium is added to the pulp solution due to contact with the feed material.

5. In another analysis of tailings from the pulp after CIP no calcium was found in solution which was construed to mean that the calcium was adsorbed onto the carbon.

6. In a test where soda ash was used to adjust pH pulp samples before and after carbon adsorption indicated that no calcium was adsorbed on the carbon. How this affected gold adsorption is not known although it is assumed that this did not solve the problem either, or else the plant would not have shut down.

7. The dump material varies in color from pale to red-yellow, brown to purple indicating significant amounts of iron in various degrees of oxidation.

8. Tests of the slimes dam material showed that cyanidation of gold in the magnetic fraction was much higher than in the non-magnetic. Adsorption of gold onto carbon from the non-magnetic fraction is poorest. Adsorption from the magnetic fraction can be improved significantly if it is roasted before leaching.

	Extraction to Cyanide Solution %	Adsorption to Carbon %	Overall Gold Recovery
Magnetics	73.2	41.7	30.6
Non-Magnetics	31.5	15.7	4.9
Roasted Magnetics	74.8	89.6	67.0

The poor adsorption from the non-magnetic fraction has been interpreted as due to adsorption of clay-like particles on the carbon which block the pores.

9. Solutions from the cyanided pulp in the tailings dam carry a considerable amount of a suspension of Prussian Blue. Prussian Blue is a complex of ferric and ferrous cyanide indicating that ferrous ions in the pulp were inadequately oxidized. This indicates that the pre-aeration step is inadequate. It is possible that some of the partly oxidized pyrrhotite in the tailings may take a long time to oxidize as the tailings contain a considerable quantity of coarse particles which could take longer to oxidize.

   Prussian blue adsorbs readily onto carbon and could well be responsible for blinding of the carbon and interfering with gold adsorption.

   It is not completely clear what can be done to remove Prussian blue from the pulp once it has formed. Very thorough oxidation of the pulp is one way to prevent its formation in the first place.

   The suggestion has been made to remove the magnetic pyrrhotite from the pulp for separate treatment to oxidize it ahead of cyanidation, possible by allowing it to weather outdoors.

10. In cyanide leach - CIP tests it was found in one test that about 900 g Mg^{2+} per ton solids went into solution and adsorbed onto carbon. Calcium dissolution from the solids amounted to 750 g CA^{2+}/t before the carbon adsorption and 1500 Ca^{2+}/t in CIP tails.

    It appears that under certain conditions magnesium and calcium in the pulp will cause carbon fouling.

11. Gold can be more efficiently precipitated by zinc than adsorbed onto carbon from solutions derived from this pulp. Reasons for this are not completely clear. Since the tailings contain a large percentage of very fine slimes, filtration is unlikely to be feasible - CCD solid-liquid separation followed by zinc precipitation is one possible solution to the problems observed above.

INTRODUCTION

Giant Yellowknife Mines Ltd. is located 62° north of the equator - just 5° south of the Arctic Circle on the northern shore of the Great Slave Lake on the outskirts of Yellowknife. Its remote location and long frozen winters are two interesting features of this gold mining operation. Giant Yellowknife Mines started this operation in 1948 and is of interest from both a gold recovery standpoint and for several aspects of how water is managed and treated in this sparse but sensitive part of the world. Because this mine has taught the industry so much about roasting and leaching of calcines from arsenopyrite concentrates it is valuable to examine the operation in as much detail as possible.

GOLD RECOVERY FEATURES

- Treatment of a low grade refractory arsenical gold ore.
- The use of roasting. Much of today's state of the art on roasting auriferous concentrates was developed at this operation. Efficient removal of arsenic from roaster gas stream is achieved.
- Gold recovery from calcines at Giant is higher than average at 92-94%. The latest leaching and solid liquid separation of the calcine is particularly interesting. It combines CCD washing with belt filtration.
- Gold recovery from precipitator dust by carbon-in-leach.
- Incremental gold recovery from the treated effluent discharge stream.
- The very low arsenic release to the environment now achieved at Giant Yellowknife would support the idea that roasting should not be ruled out in North America if a market for the sulfuric acid or SO_2 can be found.

WATER MANAGEMENT & TREATMENT

- Managing water and effluent treatment in a location where everything is frozen for over half the year.
- Removal of arsenic, base metals and destruction of cyanide in the effluent stream.
- Incremental gold recovery integrated with effluent treatment for environmental reasons.

DATE OF VISIT 7 - 8 August 1984

LOCATION 600 air miles north of Edmonton, Alberta

MINE The underground C mine and an open pit (40%) produce 1215 st ore per day for five days per week.

GRADE 0.24 oz Au/st (5.6 g Au/t) is nowadays much lower than the original operation which as long ago as 1963 processed 0.78 oz Au/t.

OVERALL RECOVERY 84 percent

ORE TYPE

Giant ore consists of sericite and chlorite schist containing a high level of free quartz, variable amounts of calcium and iron carbonates and sulfides - mainly fine-grained arsenopyrite and pyrite, with smaller amounts of stibnite, and sulfosalts of lead, iron and copper. The gold is very finely divided. Flotation concentrates would give about 30% gold recovery if leached without prior roasting.

ORE TREATMENT

Ore is crushed and ground in ball mills. Grinding is in closed circuit and after primary flotation is followed by a regrind of the tailings and a secondary flotation followed by a scavenging step. Cyanidation of tailings was discontinued years ago. 80% of the gold is recovered by a primary flotation step employing a Maxwell cell. The aim is to produce a reasonably coarse flotation concentrate at a satisfactory sulfide level while getting the best gold recovery. Overall flotation recovery is 92% down from 94%. 2-4% more gold could be recovered but not if the required 18% sulfide grade for roasting is to be maintained.

CONCENTRATE PROCESSING

About 106 st per day of concentrate at slightly below 2 oz Au/t are produced. After thickening and filtering these are blended and fed to a two-stage fluid bed roaster designed and installed by Dorr Oliver. Calcine and the coarsest dust particles are captured by cyclones from the roaster gases, quenched, reground then washed once in a thickener to remove soluble arsenic and metals, prior to leaching in cyanide after regrinding in a second 5'Ø 8' ballmill where initial cyanide and lime additions are made. According to MORTIMER & TAIT (1959) the earlier operation cyanided the flotation tailings and calcined the leached calcine for a second time in a rotary kiln, but these steps have been discontinued.

Currently a barren bleed of about 45-54% of the recirculating barren cyanide stream permits control of the undesirable buildup of copper and zinc in the calcine leach circuit. This barren bleed would have to be much greater were it not for the calcine washing step ahead of leaching.

There have been process changes since the plant was described by MORTIMER & TAIT (1959) and by FOSTER (1963). One of these is the calcine washing, leaching and flotation circuit which is now arranged as follows.

GIANT YELLOWKNIFE MINES LTD.
CALCINE LEACHING

Leached calcine still contains around 0.15 oz Au/t and represents a loss of about 15 oz Au/day. The calcine was reacted with concentrated sulfuric acid on rolls and in one test was reduced to 0.08 oz Au/t, after subsequent neutralization and cyanidation. This result however could not be duplicated in a follow up test nor when sulfurous acid was used. This incremental recovery is not considered economically attractive enough to justify additional investment.

ROASTING

Giant Yellowknife Mines achieves an excellent gold recovery from a refractory concentrate containing arsenic and antimony. Roasting practice reflects decades of effort to optimize recovery of gold. Roasting at Yellowknife has been described by MORTIMER & TAIT (1959), FOSTER (1963), CONNELL & CROSS (1981) and in general by ROSTRON (1982) three of which were included in the Randol Phase II study on "Innovations in Gold and Silver Recovery." The CONNELL & CROSS (1981) description is inserted at the end of this report.

Nevertheless, several observations were made which reflect Giant operating practice which could be of practical value: Factors of importance seem to be:

1. Feed Control
2. Roaster Condition Monitoring & Control
3. Gas Cleaning System

1) ROASTER FEED CONTROL

Maintaining Feed Uniformity

Flotation concentrate is transferred as a slurry and is screened to remove debris across a chip screen on arrival at the roaster section. Screen underflow is cycloned in an 8"Ø cyclone primarily as a dewatering measure. The overflow from the cyclone is clarified and the thickener overflow returned to the flotation plant.

Cyclone underflow and the thickener underflow are combined and split in a splitter box into three streams. The major stream goes to a concentrate storage agitator where it is constantly mixed. One stream is filtered across a disc filter and the cake pumped by a Moyno Pump (Reeves-drive) at 75-78% solids from the disc filter cake discharge to an SRL pump. The SRLC 3" x 3" rubber lined pump advances the concentrate slurry at a uniform rate to the airgun injectors to the roaster No. 1 bed.

The flow of concentrate feed to the roaster is regularly measured as the time in seconds it takes to fill a 2.01 ft^3 measuring vessel. Density is measured to compute the flow rate of concentrate feed. The feed rate in tons per hour is read off a chart, recorded and adjusted. The specific gravity of the concentrate is 3.6 dry and around 2.2 for the 78% solids slurry. A third split of concentrate is fed with the filter discharge to the Moyno pump.

The purpose of the recirculating flow of concentrate through the storage agitator is to smooth out the temporary changes in concentrate grade particularly with respect to sulfur level. By drawing roaster feed from the recirculating flow, the feed is always well mixed and changes are slow.

In the flotation plant conditions are controlled to be sure to maintain 18% S in the concentrate. Slightly higher gold recovery in the flotation step could be achieved at the expense of sulfide grade which would result in greater losses in the roasting-calcine leach end of the process. Every attempt is made to keep antimony in the concentrate at 1% Sb or less.

GIANT YELLOWKNIFE MINES LTD
ROASTER FEED ARRANGEMENT

CONCENTRATE FEED PUMPS

The Moyno pump meters the flow of concentrate whereas the soft rubber lined 3 x 3 pump provides the velocity into the airgun to the roaster.

Giant has tried several pumps to feed concentrate into the roaster. The uniform pumping rate of the Moyno pump was found to be a very good feature.

ODS pumps (air-driven diaphram pumps) were tried out but flow surges caused problems in the roaster bed.

The SRLC pump inlet is fitted with a machined high density plastic insert to prevent the inlet from rapid abrasion. The 3" inlet pipe is lined by a 1" wall tube leaving a 1"Ø inner aperture which projects right up to the SRLC pump impeller. The liner life is 2 months and it is easily replaced compared with a life of 2 weeks for the steel inlet without it.

The feed concentrate is sprayed via the air lances into the freeboard above the roaster bed.

GIANT YELLOWKNIFE MINES LTD.
ROASTING CONDITIONS

Feed rate at the time of the Randol visit was 6.11 tph solids. Roaster conditions were recorded as follows:

Stage 1

Airflow 2150 cfm at 35°F at inlet and	936° F in the bed
Freeboard temperature	757° F
Water Spray to freeboard	0.4 lgpm
Transfer Air at 413°F	

Stage 2

Airflow to bed	900 cfm
Bed temperature (NE thermocouple)	956° F
Freeboard temperarature	866° F
Water Spray	2.8 lgpm
Windbox Pressure	4.10 psi
CALCINE QUENCH WATER	75 lgpm
Water pressure	64 psi
Baghouse temperature	225° F

Specified Standard Operating Conditions are:

Feed Rate	: 6.4 tph
Slurry density	: 2.250
1st Stage Temperature	: 925° F
1st Stage Air	: 2150 cfm
2nd Stage Temperature	: 950° F
2nd Stage Air	: 900° F

Bed Density Control

Should the bed start to clinker or become non-uniform in density, gas flow will be reduced in some parts and increased in others resulting in non-uniform roasting conditions and excessive particulate flowover.

Conditions in the bed can be monitored by comparing the temperature readings from four thermocouples installed one in each quadrant of the bed. The important aspect is the spread in readings at any given time.

These are recorded, and an example of the temperature range between the four quadrants in each bed on 8 August 1984 is shown here:

ROASTER BED TEMPERATURE

Time	Roaster Bed I (Range in 4 Readings)	Roaster Bed II (Range in 4 Readings)
8 am	927-940°F	951-956°F
10 am	925-936°F	938-941°F
12 am	922-935°F	940-944°F
2 pm	928-940°F	949-953°F

Calcine Transfer

Calcine from Stage I bed is transferred to the freeboard zone of Stage II fluid bed via a Dorr Oliver vacuum Seal U-bend shown in the diagram above.

Calcine Leach Recovery

Concentrate feed to the roaster is maintained as close as possible to 18% S to allow autogenous combustion.

Antimony must be kept as low as possible, exceeding 1% as seldom as possible to avoid roaster problems.

If the ore is ground too finely then the particles are prone to be blown out of the roaster without being roasted adequately.

The roaster is operated to avoid generating pentavalent arsenic in Stage I. Oxygen concentration is kept at around 0.2% in Stage I and 1.2% in Stage II to keep the arsenic in the trivalent form. It has been speculated that if pentavalent arsenic is generated in the first stage of roast it forms ferrous arsenate which does not volatilize.

The concentrate is roasted down to 3% sulfur. If roasted beyond this, the calcine turns from chocolate brown to black as more magnetite is formed, and gold recovery by cyanidation is reduced.

The roaster controlled by varying the air, concentrate feed rate and water addition (with concentrate and as control water added as air spray to the bed). Control used to visual by on the color of the calcine, but now it is also through observing bed temperatures. Independent temperature measurement in four quadrants of each roaster bed allow hot spots to be detected early and controlled.

Corrosiveness of Roaster Gas

A gold-platinum electrode which was installed in the fluegas for O_2 analysis completely volatilized in less than a day. This observation led to the as yet unanswered question as to whether some gold is lost by volatilization to the Cottrell dust.

3) GAS CLEANING

The roaster gas train serves two main purposes. Firstly, it recovers arsenic for safe storage underground with minimal release to the atmosphere. Secondly, the gas train recovers a significant value of recoverable gold.

30,000 cfm of hot roaster gases are released up the stack at about 200° F. Gas first passes through two hot cyclones to drop any coarse particles into the quench tank with the calcine.

The gases next pass through a hot electrostatic precipitator at around 700°F at which solid particulates including gold values are dropped out. This yields about 14.5 tons per day of dust at an average of 1.21 oz Au/st, containing around 2.53% arsenic and 1.36% antimony, and thereby recovering over 90% of the gold that enters the roaster gas entrainment system. This requires careful control of the Cottrel precipitators, however.

After leaving the hot Cottrell electrostatic precipitator the gases are cooled by mixing with ambient air and at 220°F enter a baghouse where condensed arsenic trioxide is collected.

About 14 tons per day As_2O_3 is produced in this way, while only 10-20 lbs arsenic escape up the stack daily, most of the time. The arsenic dust is pneumatically transported to specially selected areas in the underground workings which are kept in permafrost condition and closed off by 12 ft concrete bulkheads from the other mine workings. The arsenic is transported to the disposal chambers via a 4"Ø feedline in and a 6"Ø return line.

The roaster gas entrainment system is driven by fans providing cooling air between the hot Cottrells and the baghouse, and by a fan at the base of the stack. SO_2 is nor removed from the roaster gases and is vented to the atmosphere. The method of condensing the arsenic dilutes the SO_2 strength to about 1%, well below the concentration of economic acid plant feed.

GIANT YELLOWKNIFE MINES LTD.
ROASTER GAS ENTRAINMENT SYSTEM

Synthetic polymer Draylon bags are used in the baghouse. The As_2O_3 recovered in the baghouse currently has an average 85-95% purity with occasional levels reaching 98% during periods of long steady state operation.

Arsenic emissions from the stack were found to occur mainly when the bags were being shaken. These emissions were dramatically reduced by converting the shake cycle from one that was timer controlled to one that was pressure drop activated. By setting a 2 inch water gauge pressure drop the bags are now shaken four times a day - a reduction from 16 cycles when the system was timer controled.

The arsenic oxide baghouse dust is transported to the permafrost stopes pneumatically using a Fuller-Kenyon pump.

Fuller Corporation
County Line Road
Bethlehem, PA

(215) 264-6011

A large truck-mounted vacuum cleaner for dust collection is maintained on the site for use in the event of a dust spill. Provision is made for the vacuum truck to unload to the arsenic storage bins.

COSTS

Labor base rate at Giant Yellowknife is C$16/hour. When workers are exposed to high arsenic areas they get paid 250% of their normal wage. However, they have available the latest protection equipment as this mine was the location for a National Task Force in Arsenic Exposure in 1976.

Because of the location most items are more expensive at Yellowknife than in the main industrial centers. For example lime costs C$241.80/ton or C$0.121/lb, and NaCN C$0.86/lb.

COTTRELL DUST TREATMENT

Cottrell dust is slurried, screened and leached with cyanide for about 6 days in the presence of carbon. Carbon-in-leach results in a better recovery than conventional leaching. The use of carbon is also necessary as the dusts are ultra-finely divided and neither settle nor filter well. This circuit recovers 85% of the gold contained in the Cottrell dust feed.

FOSTER (1963) showed that recovery of gold from this dust is sensitive to the type of alkali used and that with no alkali addition at all, gold recovery was actually the best but cyanide consumption went up to 53.5 lbs NaCN/ton.

The dusts are discharged from the Cottrell hoppers by screw conveyors into enclosed agitators, and pulped with water to 10% solids by weight before being pumped to a 30ft diameter storage thickener. The dust slurry has a pH of 5.0, is highly viscous and almost impossible to filter. It settles overnight to 50% solids however.

Each day a measured volume of pulp from the storage thickener is pumped to a conditioner where it is sampled for assaying and neutralized to pH 9.8 by addition of NaOH, Na_2CO_3 and Armac HT. After conditioning this goes to 2 (20'Ø x 25' h) agitators for pre-carbon cyanide-leaching for about 6 days. This has not significantly changed overall recovery.

An equal quantity of cyanided pulp is added to the first of two carbon in leach agitators in series which are operated on a batch basis. Residence in the CIL tanks is 72 hours.

Barren pulp is discarded from the second CIL tank after recovering carbon by screening which is returned to the leading CIL agitator. 120 lbs. fresh carbon is added daily to the tail agitator to scavenge gold from the pulp.

Discarded pulp contains 0.0002 oz/t Au (0.006g Au/t) in solution and 0.23 oz Au/t in the solids.

When carbon in the leading CIL agitator reaches the desired gold loading which normally occurs bi-monthly, it is removed by screening the pulp and washed to remove slime before being dried in a steam drier to 2 percent moisture for shipment to a smelter.

Parameters of the 1984 Cottrell dust processing are:

SOLIDS TONNAGE	: 14.50 stpd
PULP DENSITY	: 50% solids SG 1.518
PULP TONNAGE	: 29.7 stpd
LEACHING pH	: 9.8
LEACH RECOVERY	: 85%
CARBON TYPE	: CALGON CARBON (delivered cost $1.68/lb)
CARBON CONSUMPTION	: 18t in 1983
CARBON COST	: $1.68/lb delivered (estimate)

	Tonnage Stpd	Au (oz/t)	As (%)	Sb (%)	Au (distribution)
Dust Feed	14.50	1.21	2.20	1.36	100.00
Solids in Tails	11.34	0.23			14.86
Barren Solution	19.46	0.0002	983ppm		0.22

REAGENT CONSUMPTION	lbs/day	average lbs/ton
NaOH	14.50	1.00
Na_2CO_3	72.00	5.00
NaCN	180.00	12.82
Amine Acetate	11.60	0.80
Carbon	120.00	7.96

Amine acetate is added as it seems to improve gold leaching, possibly by reducing the surface tension allowing cyanide to penetrate pores better. The mechanism for this is not clear.

HCN MONITORING

The CIP plant building is enclosed to conserve heat in the cold climate so it is important to monitor HCN levels in the air. This is done with a Draeger sampling tube. Only on one occasion in the last 8 years has the HCN level reached the threshold level value for safe exposure of $10mg/m^3$. This occurred when the emission duct from a tank fume hood fan ruptured at an elbow joint.

HISTORICAL DATA

Data from FOSTER (1963) showed that the leaching and carbon adsorption recovery of gold from the Cottrell precipitator dusts is sensitive to the type of alkali used.

EFFECT OF VARIOUS ALKALIS ON GOLD EXTRACTION

		(1963 data)				(current)
		Nil	CaO	NaOH	Na_2CO_3	
Dust Au	(oz/st)	3.85	3.85	3.85	3.85	1.21
Residue Au	(oz/st)	0.5	1.41	1.13	0.72	0.23
Barren Solution	(oz/st)	0.005	0.016	0.021	0.009	0.0017
Gold Extraction	(%)	87.01	63.37	70.65	81.29	85%
Reagent Consumption						
NaCN	lb/t solids	53.5	7.5	9.3	12.5	12.4
Alkali	lb/t solids	-	9.5	8.1	40.5	6.0
Carbon		10.0	10.0	10.0	10.0	8.3

INCREMENTAL GOLD RECOVERY : TAILINGS EFFLUENT

After the tailings dam is decanted and the water treated by alkaline chlorination and ferric flocculation for cyanide destruction and arsenic precipitation, the decant pond overflow is gravity fed to carbon adsorption columns for incremental gold recovery. It was not determined whether the full flow of effluent is treated in the carbon adsorption columns. Fragments of information on the carbon columns are summarized as follows:

Number of Columns: 3 stages

Design of Columns: Upflow Cortez type columns with 2 % open area in plate distributors. (unconfirmed open area)

Feed Solution Tenor: pH 7.5
Au concentration 0.0008-0.002 oz Au/t

Carbon Loading: Adsorption Stage I 60 oz Au/t

Carbon Consumption: 20 tons for 1984

Tailings Solution Flow Rate: In 1983 a total of 312,000,000 lg (1,415,223 m^3/a) of effluent were treated and discharged, which had a gold content of around 3000 oz per year and is clearly a worthwhile target.

Carbon Elution: Formerly loaded carbon was shipped to a smelter by road in 2-3 ton shipments. In 1983 18 tons of carbon were shipped to ASARCO in 10-11 shipments packed in steel drums. Carbon freight costs at C$344/t and the additional cost of the carbon smelted, 5 month wait for payment and a recovery charges work out to over $5000/ton carbon making this an expensive route. Giant is currently evaluating an elution and regeneration system, and in the meantime is shipping their loaded carbon to a custom elution plant:

DISCUSSION

(1) Gold adsorption to 65.85 oz/st carbon from solutions with tenor as low as 0.0008-0.002 oz Au/st is evidence of the positive influence on adsorption of reducing the pH, removing most free and complexed cyanide and removing the base metals from the feed solution. These factors were discussed in the RANDOL (1983).

(2) The Giant tailings are frozen for much of the year. Even in summer only the upper layers thaw so the decanted solution drained from tailings is relatively cold. At low solution temperatures the density is higher and must be taken into account when designing fluidized bed adsorption units.

(3) Giant has experimented with several adsorption systems and has found that unless the carbon is fluidized correctly adsorption recovery is poor.

(4) Economics of elution and regeneration of carbon on a small scale is poor considering the capital costs involved and labor factor. For a conventional elution plant and regeneration kiln to treat 1 ton carbon per week, the Falconbridge preliminary capital cost estimate was around C$400,000. Meanwhile, a simpler elution system design has been found with indications that regeneration may not be essential.

TAILINGS DAM

The 200 acre tailings dam at Giant Yellowknife was originally a lake into which tailings were pumped and solutions decanted via Baker Lake to Great Slave Lake. The pond has been in use since the mine started up in 1948, and dam walls have been built to expand its capacity since then.

Dam walls are built of wasterock with a clay core and wasterock riprap. The lower levels of the waste pond are frozen yearround and only the top 3 or so feet thaw in summer.

Initially the tailings entered the dam at the end closest to the mine so the pond was at the far end against a relatively porous wasterock wall. The tailings site in 1945 was selected and used without geotechnical surveying. Seepage remains less than 5 gpm.

Since 1979 seepage has been collected from cutoff trenches and pumped back to the dam in the summer months. In 1983/4 tailings were discharged to the pond at the far end by spiggoting at the dam wall. The result has been a noticeable drop in seepage rate. It requires an extra mile of tailings line. Sclair pipe is used. In winter the tailings are discharged at the plant end of the dam also through a sclair pipe line. Below the dam wall there are two seepage collection points including a collection trench and beyond that a concrete dam to bedrock to trap seepage. Still there is evidence of some low level seepages from the ground beyond these two protective devices, but these are intercepted.

Tailings include all flotation waste, calcine washings, calcine leach tails, precipitator dust washings, precipitator dust CIP tails and the Barren bleed.

TAILINGS DAM WALL AND SEEPAGE CONTROL

WATER MANAGEMENT AT GIANT

Water is abundant in the Northwest Territories and Giant being located almost on the Great Slave Lake is close to an abundant supply. The only limitations on fresh water use are:

1) The cost of pumping it from the lake
2) The cost of treating it prior to discharge
3) The Northwest Territories Water Board license limitations on total fresh water use which currently allows 1,950,000 m^3 per year including mine drainage water.

Giant's overall water consumption is close to the limit re 1,950,000 m^3/year for 325,000 short tons ore/year mined, works out to 6.6 tons of water per ton ore mined.

HALVERSON & CROSS (1984) outlined a flow diagram of water and typical analyses of effluents as shown above. PRICE (1981) described the pilot treatment plant results and the rationale behind the process solution and the location of the treatment plant.

From this data and from the point in the flow of water that the treatment plant was inserted it is possible to conclude that:

1) The main water management objective came about in 1980 when within a year the arsenic, cyanide and base metals had to be significantly reduced in the tailings dam effluent to meet operating permits.

2) Although the most serious contribution to arsenic, cyanide and base metals are relatively small flows, their isolation for separate treatment in a small plant could do little in the short term to treat the water already in the large 200 acre pond which was well in excess of the limits that had been set.

3) The gold price was projected to remain high.

4) Consequently Giant Yellowknife installed a process for high pH chlorination followed by ferric flocculation which were the only proven technologies available at the time.

5) The plant is designed to treat the full annual flow of tailings decant solution over a six month operating season.

6) Tailings dam water containing 8.6 ppm CN^- is not suitable for recycle to the mill for the main water consuming step, namely flotation, because cyanide depresses pyrite which the plant tries hard to float.

7) Use of minewater in the flotation plant has been found for as yet undefined reasons to result in unsatisfactory results. Use of minewater in the flotation plant was tested to result in a 1% drop in gold recovery values at $30,000/month. Possibly the small cyanide values or oil and grease in the minewater are the problem.

8) Water is used to wash calcines and precipitator dusts prior to cyanidation to remove cyanicides and elements that interfere with gold precipitation.

9) Copper and Zinc are bled from the calcine leach circuit by discarding a 10% barren bleed to tailings.

10) In the existing arrangement, all contaminants are directed to the tailings dam and the whole volume of effluent treated. Since the tailings effluent must be treated anyway, the economics of separately treating a small segregated stream of the more concentrated effluents would have been impractical.

11) If one was to have an opportunity to design the whole mine-mill complex over from grass roots in today's environmental climate, it might well prove possible to keep the flotation tailings separate and cyanide-free allowing water recycle to the mill a very much reduced effluent treatment plant. However, then additional capital would be required for separate storage reservoirs.

12) In the past minewater averaged 1.72 ppm CN_T implying it gets there either with sand backfill or via seepage from the tailings dam. Minewater today no longer has a detectable cyanide level.

INFLUENCE OF COLD CLIMATE

1) Because the tailings pond is covered in snow and ice and because the water treatment plant would be too expensive to heat, it is operated only for the six warmer months from late spring to fall. This means that the tailings dam must be large enough to contain the tailings and precipitation plus spring thaw runoff. The latter is controlled to be very small.

2) During cool weather the oxidation reactions, precipitation and flocculation of precipitates is likely to be slowed down.

3) Because of the cool climate natural degradation of cyanide in the tailings pond will be slower than in a warm climate which means that there will be more cyanide in the final effluent to destroy. The large surface area of the tailings and decant ponds and plenty of wind makes up for this to a degree, however.

4) At the very cold water temperatures in the Giant tailings effluents, solution densities will be higher than at warmer temperatures. This must be taken into account in the design of fluidized bed adsorption columns.

5) The tailings are discharged to the tailings pond at the end nearest the plant i.e,, furthest from the dam wall, in winter to avoid problems of freezing in the extra mile of tailings line to the dam wall. This was true prior to the installation of a new "South" tailings dam.

MINE DRAINAGE WATER

In the late 1970's prior to installation of the Effluent treatment plant, Mine water had the following composition. (Listed for interest sake.)

pH	7.86	
Specific Conductivity	2.96	millisiemens/cm
Suspended Solids	45	ppm
AS_T*		8.92
CN_T	1.72	(0.6 -2.4)
Cu_T	1.31	(0.15-1.94)
Ni_T	0.55	(0.10-0.99)
Fe_T	3.63	(0.43-8.6)
Zn_T	0.18	(0.09-0.46)
Pb_T	0.10	(0.06-0.31)
Oil & Grease	1.03	
SO_4 ppm	734	
Cl^- ppm	706	
Hardness ($CaCO_3$)	960	
Alkalinity ($CaCO_3$)	136.9	

* The mine is located under Baker Creek and with workings adjacent to and under the final effluent pond. Since effluent has been treated however, minewater cyanide content has dropped to less than 0.01 mg/l.

Prior to 1980 effluents to Baker Creek which accounted for about 30% of its total flow to Yellow Knife Bay contained 20 - 35 mg/l CN^-.

WATER BALANCE DATA

A typical summer and winter water balance for the Giant Mine-Mill is as follows:

		July 1984 Summer (lgpd)	Jan 1984 Winter (lgpd)
A.	Yellowknife Bay Main Pumphouse to "C" area	722,610	926,803
B.	To Underground "A" Shaft 43-10	Ø	Ø
C.	To "A" Boiler	Ø	5,293
D.	To Diesel Plant	Ø	Ø
E.	To "C" Boiler	10	[illegible],610
F.	Total from Yellowknife Bay Main Pumphouse	722,610	926,803
G.	To Underground "C" Shaft 43-3	38,387	37,252
H.	From "C" Shaft Mine Discharge 43-2	420,490	295,071
I.	From Yellowknife River (domestic water)	81,539	121,616
J.	Wastewater Campsite to Mill Tails Box	79,908	Ø
K.	To Mill Process (+T)	Ø	Ø
L.	Estimated Seepage into Mine [H-(B+G+D)]	382,103	257,819
M.	Total Water Used A + L + I	1,186,252	1,307,239
N.	"C" Compressor Water Mill Process	110,935	138,652
O.	Tons Milled per month	26,529t	21,992t
P.	Arsenic Pumped u/g (lb/mo)	504,090	530,294
Q.	Tails Decant to Baker Creek (lgpd)	2,108,119	Ø

CARBON LOADING

	Analysis of Gold Laden Carbon (1963 data)		
Gold	Au	466.0	oz/st
Silver	Ag	95.0	oz/st
Arsenic	As	3.80%	
Antimony	Sb	2.75%	
Moisture	H2O	7.00%	

CARBON SELECTION

Various carbons have been used for gold adsorption in this plant over the years. FOSTER (1963) indicated that NORIT 8 X 20 mesh carbon made in Florida from pine wood was preferred. In recent years several varieties of coconut shell carbon have been tested and the current favorite is a Calgon carbon.

EFFLUENT DISCHARGE TO BAKER CREEK BEFORE TREATMENT PLANT

	CN^-	As	Cu	Pb	Ni	Zn	S/S
Tons/Year Discharge	23.1	17.04	13.47	0.083	1.75	0.54	4.31

WATER QUALITY AT BAKER CREEK BEFORE WATER TREATMENT

	1978 Tails Discharge to Creek	1978 Creek Discharge to Lake
pH	7.86	8.04 (ave)

Suspended Solids	4.78	11.59 ppm
AS_T	21.25	7.42 ppm
CN_T	27.52	1.61 ppm
Cu_T	15.55	2.97 ppm
Ni_T	1.88	0.80 ppm
Fe_T	1.08	1.43 ppm
Zn_T	0.65	0.24 ppm
Pb_T	0.10	0.05 ppm
Oil & Grease	1.77	1.38 ppm
$SO_4^=$		766. ppm
Cl^-	112.8	215. ppm
Hardness (as $CaCO_3$)	438.7	400. ppm
Alkalinity (as $CaCO_3$)	37.14	90.4 ppm

REGULATORY AUTHORITY

The Northern Inland Waters Act came into effect in 1976 and required a water use license for mining operators. The regulating authority is controlled by the Federal Government and is:

Northwest Water Board
P. O. Box 1500
Yellowknife NWT XIA 2R3

(403) 920-8191
Telex: 034-45623

Glen B. Warner, Chairman

PERMIT DETAILS

The permit specifies progressively strict limits for the main contaminants in the tailings effluent. After May 1, 1982 the following limits have been in effect:

	Max Average Concentration	Max Conc of Any Grab Sample
Total CN	1.5 ppm	3.0 ppm
Total As	0.8 ppm	1.6 ppm
Total Cu	0.8 ppm	1.6 ppm
Total Pb	0.2 ppm	0.4 ppm
Total Ni	0.5 ppm	1.0 ppm
Total Zn	0.2 ppm	0.4 ppm
Suspended Solids	15.0 ppm	30.0 ppm
pH	6.0 ppm min	6.0 ppm min

No floating solids, no visible oil or grease.

After May 1, 1984 the following additional limits have been added

Total Residual Cl_2	0.1 ppm	0.2 ppm
Ammonia (NH_3-N)	1.0 ppm	2.0 ppm

This average limit for ammonia of 1 ppm as N is relatively low and likely to be difficult to meet. Ammonia is probably added through minewater as a result of underground use of explosives and may also be added through release of sewage waters to tailings.

A 1 ppm N standard for NH_3 is a lot lower than most sewage treatment plant discharges in Canada. This is the only parameter of their license that is not met at present.

Residual chlorine at 0.2 mg/l is also a low level. Cl_2 is however toxic to fish down to 10 ppb which is a factor of 20 lower than the effluent limit, but a means of measuring Cl_2 below 0.1 mg/l are not readily available.

Environment Protection Service of Canada performed bioassay tests on Giant treated effluents in 1983. The rainbow trout test fish were killed until thiosulphate was added to consume the excess Cl_2.

It is noted that Giant has installed carbon columns at the overflow of the decant pond to recover incremental gold values. Activated carbon at the pH range of decant pond water should reduce chlorine to chloride, although this effect has not been monitored.

A bond of $150,000 has been deposited with the NWT Water Board to guarantee performance of the water effluent treatment.

ANALYSIS METHODS

Chlorine

A disposable rapid method for Cl_2 level analysis is available from:

Park Davis & Co.
11471 Vanowen Street
P. O. Box 9338
North Hollywood, CA 91609

(213) 765-7830

The test is known as the Water-Chex color comparison test for chlorine at 0 - 11 ppm. It is an aseptic-Thermo indicator which changes color proportionately to the Cl_2 level in the test solution.

The Water-Chex chlorine test kit is available in Canada from:

Miller Williams Hydronics Ltd.
4060 Fairview Sreet, Unit 12
Burlington, Ontario L7L 4Y8

(Catalog No. 00200)

This test is good only down to 1 ppm which is useful only for spot checking solutions and effluents for very high levels of Cl_2.

Giant Yellowknife Mines determines Cl_2 down to 0.1 ppm using a Hach Kit, available from:

Hach Company
P. O. Box 389
Loveland, CO 80539
USA

(303) 669-3050
Telex 910-930-9038

Arsenic

Arsenic is determined down to the parts per billion level using the AWWA color reaction with silver diethyl dithio carbamate to measure As in a spectrometer. This method is available (U.S. $60) in "Standard Methods for Wastewater Analysis," 15th Edition from:

American Public Health Association
1015 15th Street NW
Washington, DC 2005

(202) 789-5600

American Water Works Association
Vermont Avenue NW
Washington, DC
(202) 628-8303

$60.00

WATER TREATMENT PLANT

The selection of the water treatment process was made on the basis of pilot and laboratory testwork of available processses at the time when a final decision had to be made. The point at which it was inserted was due to the immediate need to improve effluent quality and because the existing tailings dam contained a large inventory of contaminated water which did not meet the new effluent standards. These factors are discussed by PRICE (1981), who also predicted capital and operating costs for the new plant. At the time it was expected that $400,000/year was a conservative estimate. Compare actual costs with projected:

	Plant Throughput	$[CN_T]$ ppm	[As] ppm	Capital Cost	Operating Cost Annual	C$ per 1000 gal.
1980 Estimate	1,476,000 lgpd	25.53	10.55	C$1,500,000	C$400,000 max	C$1.50
1983 Actual	312,000,000 lg in 6 months 1,750,000 lgpd	8.6	12.1	C$2,000,000	C$780,500	C$2.45

A detailed description of the design and performance of the actual water treatment plant by HALVERSON & CROSS (1984) is inserted below. This provides an excellent insight into how performance varies as operating parameters are changed. It shows in particular how reagent consumptions need to be considerably more than the theoretical requirement to achieve the design results.

Here are a few additional observations.

1) A Sulfuric acid tank is installed at the water treatment plant, the plan had been to use sulfuric acid to drop the pH of solutions to 8.5 after ferric sulfate addition to aid arsenic precipitation which requires this pH for optimum precipitation.

   In fact it is found that the ferric sulfate additon is itself adequate to drop the pH to 8.5.

   In the pilot plant which was tested at higher arsenic levels, so much ferric sulfate had to be added that the pH dropped below the optimum pH 8.5 - down to pH 4 in fact, and lime had to be added to bring the pH up. The full scale plant did not have a lime system for the second reactor so ferric addition is added only until the pH is brought down to 8.5.

   In the plant since As levels are lower and less ferric sulfate needed, pH does not drop too far.

2) The plant achieves As removal to 0.14 ppm at a ferric sulfate addition of 7:1. This is considerably lower than the limit called for of 0.8 ppm As in the license. Consequently $Fe_2(SO_4)_3$ addition will be economized by cutting it back to 5 or 6:1 which is not adequate to bring the pH to 8.5. H_2SO_4 could be dosed to achieve this however.

3) The CN-As treatment plant precipitates copper, zinc, lead and arsenic. Much of the nickel goes through as [Ni(CN)n].

   Ferro and Ferri cyanides are difficult to destroy and in fact probably remain in the effluent. Ferro/Ferri cyanides report in the CN_T analysis, but not in the weak acid dissolvable analysis for cyanide.

4) Co, Ag, Au cyanides are not detected in the CN_T analysis.

5) Plastic PVC lines manufactured by Pacific Plastic Co. were installed to dose sulfuric acid. Up to 25% of the plastic turns out to be a $CaCO_3$ filler, which dissolves when acid is added. A viscous white sludge has fouled the lines when the acid has been dosed completely blocking acid flow. It is important to correctly check material specifications. The complete acid piping system at Giant needs to be replace because of this pitfall.

6) A Hypalon lining has been installed over an earthen berm as protection against an acid spill from the tank. After 4 years glue failure is observed on all the lining joints indicating that plastic lining installation technology is not yet perfect.

7) Grit in both the lime and ferric sulfate clogs the BIF pumps. The BIF (Basics in Flow) pumps work with a diaphram and a ball valve which is essential to the pumping action. Grit gets into the ball valve and prevents it from closing - rendering the ball valve inoperable. Ferric Sulfate is now dissolved in a batch tank to settle out grit which can be removed by periodic flushouts. Ferric sulfate is too corrosive to be easily screened across available metal screens.

8) Ferric Sulfate is difficult to work with. It is very corrosive to most metals. The ferric sulfate does not dissolve readily and the drains in the plant get clogged. Open trench drains are needed which can be easily cleaned out.

9) Grit traps are considered essential ahead of any pumps. These traps must be PVC or stainless steel screens able to withstand $Fe_2(SO_4)_3$ corrosion. Ferric Sulfate corroded a ½" steel strainer within one 8 hour shift.

10) Three large reagent tanks are installed in the water treatment plant, each is about 10 ft Ø X 10 ft high made of 3/16" steel, one each for:

Ferric Sulfate Solution
Percol Solution
Lime Slurry

11) Allied Colloids PERCOL polymer flocculant is dosed with the ferric sulfate as a very dilute solution 4 lbs flocculant is added to 1000 gallons water in the mix solution. This is added to the third tank at a rate matching the ferric solution (dual head pumps); the mix strength is a function of flow.

12) The same BIF pump doses both ferric sulfate solution and flocculant, in separate delivery lines.

GIANT YELLOWKNIFE MINES LTD
EFFLUENT PLANT REAGENT DOSING

BIF: Basics In Flow
Division of General Signal Corporation
Division Road
West Warwick, RI
(401) 885-1000

13) The water treatment plant is located some distance from the main operations. To save need for fresh gland water for the lime solution pump, a grease seal has been installed. One cylinder of grease lasts 3 - 4 days.

14) The concentrated H_2SO_4 solution is dosed via BIF pumps which are installed in rubber lined concrete sumps as a protection measure. These pumps have yet to deliver one tank full of acid. The rubber lining has failed.

15) Cl_2 dosing is accomplished by a system supplied by:

Wallace & Tiernan
Division of Pennwalt Coporation
25 Main Street
Bellville, NJ
(201) 759-8000

This system has proven satisfactory. It has proved to be better than the Fisher-Porter Cl_2 dosing system installed at a Westmin Resources plant on Vancouver Island which reputedly has given poor service. Giant installed a W & T Cl_2 dosing unit after visiting Westmin Resources facility in 1980.

16) The Wallace & Tiernan chlorine dosing systems employs cathodic protection to prevent corrosion. Na_2SO_4 is dosed to increase conductivity for this purpose.

Electrodes prevent Cl_2 from oxidizing the pipeline. An automatic pressure sensing device allows the system to switch over from an empty Cl_2 cylinder to a new cylinder when empty (or if the gas pressure drops below a preset threshold for any reason.)

17) The welded steel pipelines for Cl_2 dosing must be replaced every 5 years. Also, one cannot weld a steel pipe with Cl_2 in it because this sets off an oxidation reaction inside the pipe, which being exothermic is self sustaining as long as the supply of iron and Cl_2 lasts.

18) 2500 lbs liquid Cl_2/day are consumed at the plant. It is delivered from liquid chlorine via a gasifier as shown schematically below.

GIANT YELLOWKNIFE MINES LTD.
EFFLUENT TREATMENT REAGENT ADDITION

19) The water treatment plant is operated for 6 months/year only. There is a problem hiring operators just for 6 months.

Three of the mill personnel have been trained in the operation of the water treatment plant. These are able to train the seasonal employees.

The plant requres 1 operator/shift, working two 12 hour shifts. Plant operators in the NWT receive C$14/hour with $0.75/hour extra for nights and afternoons or $1.50/hr extra for weekends. They work 4 days on, 4 days off.

Operators net about C$2000/month working 4 days on and 4 off alternating between day and night shift.

20) When the $Fe_2(SO_4)_3$ is first mixed it appears to be a milky suspension. After aging for a couple of hours it changes to a dark brown color. The $Fe_2(SO_4)_3$ supplier is in Tennessee and the product performance seems to vary from batch to batch.

1984:	Need 4 bags/day
1983:	Needed 6 bags/day

21) When $Fe_2(SO_4)_3$ is used it helps keep the pH probe clean. Operators clean the pH probes every second day with 25% HCl.

22) The plant was designed to be operated by only 1 dayshift operator. The enunceator system on the controls has not worked well and full time operator supervision has beer. required.

23) If the plant were to fail only for 1 hour in 24 it would result in a doubling of the As and CN^- level in the decant pond. Therefore it needs constant surveillance.

24) The three outdoor reaction tanks have drains connected to a sclairpipe header. Shrinkage and movement in winter breaks the line which is connected to the three tanks.

25) FRP walkways are used. These are expensive but have not corroded.

26) The Ferric Sulfate solution tank was made of steel lined with FRP. The lids of the tank corroded off and have been replaced by FRP. All in-plant piping uses PVC.

27) The pressure reducing relief valves in the plastic piping system clogged with grit after the plant was started up and has been useless.

28) The PVC piping throughout the plant is arranged along piperaces in such a way that it is extremely difficult to work on any one line. The pipes are too close together with too many fittings of glued joints. Threaded fittings could be replaced if one were to break at freezeup. In the present design, if one breaks 5 or 6 have to be replaced to get to the broken one.

29) Lime is fed via a rotary valve at the bottom of the lime silo which is operated for a timed period to add lime. The original volumetric feeder gave trouble and has been discarded. The lime silo and feeder was supplied by PEABODY ENGINEERS.

30) Numerous salts were tried out benchwork, leading to the pilot plant design, including:

Ferric chloride
Alum
Ferric Sulfate
Ferrous Sulfate
Lime

Ferric Sulfate addition gave the best results for arsenic oxidation.

Benchscale testwork over 2 years yielded valuable data but was not written up. It was carried out by Dr. Brian Leclair who left the Canada Centre for Inland Waters in Burlington for Ottawa then to Wolsous, Canada but has subsequently left there too and could not be traced.

INTRODUCTION

Homestake Mining Company in Lead, SD is still the largest gold producer in the USA and needs no introducing. It is also one of the oldest operations and is the only known example where percolation leaching of sand after a sand-slime split is still practiced. Flow diagrams are inserted below.

From a water management point of view, however, there are four main points of interest:

1. The pioneering use of engineered bacterial processes for detoxification of effluents.

2. The development of a quantitative in situ site specific bioassay technique to test the environmental compatibility of treated effluents.

3. The effect of new underground mining techniques on metallurgical processes due to an impact on water quality.

4. Development of effluent discharge regulatory limits for the Homestake operation, from the regulator's standpoint.

1. EFFLUENT TREATMENT AT HOMESTAKE MINE, LEAD, SD

Homestake processes about 6000 tons per day of ore. After a sand-slime split the sand is percolation leached in vats and then after washing it is pumped back underground. About 2500 tons per day of slimes are agitation leached using cyanide, after being throughly pre-aerated to oxidize pyrrhotite. The leached pulp is then subjected to carbon in pulp to recover leached gold values. Finally the slime tailings are pumped to a tailings pond in Grizzly Gulch.

The Homestake Mine requires pumping and on account of residual cyanide in the sand fraction the underground minewater contains some cyanide and metals which exceed the levels that can legally be discharged. The tailings pond decant water also contains cyanide and metal values requiring treatment before they can be discharged. Typical analyses of Homestake's effluent flow streams are compared with their NPDES permit as documented by EDELMAN & WALLINE (1981).

The treatment plant must be able to treat up to a maximum of 21,000 m^3/d of combined effluent to render it suitable for discharge into Whitewood Creek which is a cold water marginal trout fishery.

In order to try and meet the NPDES permit requirements Homestake Mining Company has tested virtually every cyanide destruction method ever developed. In their case the minewater is warm and this has allowed them to consider the use of bacterial processes. The water from underground and the tailings decant is combined and has the following typical characteristics as reported by MUDDER & WHITLOCK (1984).

Parameter	Value*
CNS	45.0 - 75.0
CN_T	0.50 - 10.0
CN_C	0.50 - 5.00
Iron	0.50 - 2.00

REQUIREMENTS OF PROCESS FOR CYANIDE TREATMENT

In comparing the characteristics of effluent streams with the required effluent limits it is clear that the levels of several species in addition to cyanide must be reduced, for example copper and zinc. In addition ammonia levels of 5.0-6.0 ppm and high CNS^- values indicate that possibly these species should also be reduced in order to improve the effluent quality with respect to its impact on aquatic life.

PROCESSES TESTED

MUDDER & WHITLOCK (1984) tested just about every cyanide treatment process available except the INCO SO_2 process, including:

- Ozonation
- Acidification/Volatilization
- Carbon Adsorption
- Ion Exchange
- Alkaline Chlorination
- Copper Catalyzed hydrogen peroxide with ferric chloride addition.

Alkaline chlorination failed on account of its inability to remove total cyanide, i.e., ferrocyanides. MUDDER & WHITLOCK (1984) indicate the reasons for rejection of all of the other processes. In addition they compared results achieved by various biological processes and describe the development of a two step biological process first to remove cyanides and metal and then to remove ammonia.

BIOLOGICAL PROCESS

The bacterial process employing Pseudomonas paucimobilis for cyanide oxidation is described by MUDDER & WHITLOCK (1984) and WHITLOCK & MUDDER (1984). Nutrient supplements of soda ash and phosphoric acid are added in a controlled dosage and the plant layout, as illustrated by MUDDER & WHITLOCK is shown below.

The biological process was shown in the laboratory and in a pilot scale operation employing a 2.0 m Ø biodisc to achieve excellent results for total and free (Method C) cyanide, thiocyanate removal, as well as removal of ammonia and copper. Test results shown by MUDDER & WHITLOCK are listed below as well as results of the commercial plant reported by SCOTT (1984):

	PILOT PLANT		COMMERCIAL PLANT	
		2M Ø RBC		12' Ø RBC
	INFLUENT	EFFLUENT*	INFLUENT	EFFLUENT*
	MUDDER & WHITLOCK (1984)		SCOTT (1984)	
Thiocyanate	60.0	1.0	50.0	0.3
Total Cyanide	6.5	0.35	2.0	0.02
Free Cyanide (Methoc C)	4.1	0.05		0.10
Ammonia N	6.0	0.50		0.5
Copper	1.0	0.06	1.0	0.05
Suspended Solids	-	-	-	10.0

* Values in ppm

The pilot RBC plants were furnished by ENVIREX. The original feasibility study was undertaken with the use of a 0.5 m Ø RBC pilot plant. The 2.0 m Ø pilot plant was operated with the first and second stages unbaffled. Supplemental aeration was fed to each stage of the pilot plant at an equivalent rate of 0.07 m^3/s (150 cfm). Stripping of biomass required 0.283 m^3/s (600 cfm). The total surface area of the pilot plant was 743 m^2 (8000 ft^2). The pilot plant was operated at flow rates of 0.13-0.50 l/s (2.0-8.0 gpm). Effluent values recorded above were obtained on clarified and sand filtered effluent by MUDDER & WHITLOCK (1984). Nitrification is the rate controlling step in the overall design.

The full scale biological treatment plant includes the following steps as shown schematically by SCOTT (1984).

1. Addition of phosphoric acid and soda ash
2. 48 rotating biological contactors with supplemental air
3. Ferric chloride and polymer addition
4. Clarification in a cylindrical clarifier
5. Emergency clarifier
6. Sand filtration
7. Discharge to stream

The full scale RBC's were supplied by:

At the time of writing this innovative new cyanide destruction plant - which should really be looked upon as an effluent treatment plant because it takes care of a spectrum of undesirable contaminants - was still in the commissioning stages and Homestake Mining Company has yet to release the final performance data.

It was found that calcium in the minewater which was introduced in part by cement addition in the mine backfill has resulted in an interfering scale on the biological contactors. As of December 1984, Homestake has embarked on a 90 day period during which no cement is added to the backfill as an experiment to see what effect this has on the biological effluent treatment plant results.

From the point of view of using bacterial processes, Homestake is fortunate in that minewater is heated underground so that the mixed mine and tailings effluent temperature is favorable for biological processes yearround despite the cold winters in South Dakota.

The capital cost of the 21,000 m^3/d (5.5 million gpd) biological treatment plant is around $10 million.

Design operating costs are around $500/day although at this point in time during the optimization program the costs are somewhat higher than this. This is a remarkably low cost which works out to less than $0.10/ton ore or $0.25/m^3$ effluent treated compared with other processes which have been reported to cost around $1.00/ton ore and more, as for example the Ok Tedi process using peroxide.

2. SITE SPECIFIC BIOASSAY TOXICOLOGICAL TESTING

WHITLOCK & MUDDER (1984) describe an in situ site specific bioassay method that has been developed and demonstrated at Lead. MUDDER et al. (1984) have described how their technique is being used to develop site specific discharge criteria through toxicological testing.

Employment of aquatic toxicological testing for the selection of viable wastewater treatment alternatives and the development of site specific water quality criteria is increasing. The increase in its use is due to its cost effectiveness in solving environmental problems and it is proposed as a viable practical tool for use in commercial plants.

MUDDER et al. (1984) describe a new approach which follows flexible guidelines recently proposed in a new water quality development document published by the EPA. Discharge criteria based on general numerical standards often seem to include relatively broad safety margins. Site specific toxicological testing as developed at Homestake's Lead operations make it possible to demonstrate that an effluent is or is not compatible with the designated use classifications of Whitewood Creek which is the receiving stream. The need for this approach has been amply demonstrated at Homestake's Lead operation where no known processes are able to meet the original NPDES discharge criteria. However, biological effluent treatment using the new Homestake process yields an effluent that with the use of the site specific toxicological test demonstrated by MUDDER et al. (1984) can be shown conclusively to be environmentally compatible.

According to Consent Decree, Civil No. 78-5094 of United States of America, State of South Dakota vs. Homestake Mining Company, February 1980, if the treated effluent discharged by the mine can be shown not to interfere with the attainment and maintenance of the existing designated beneficial uses of Whitewood Creek under South Dakota water quality standards, the state will initiate proceedings to consider modification of its water quality criteria for Whitewood Creek.

Based on a $300,000 bioassessment of Whitewood Creek in accordance with proposed EPA guidelines and protocol, by a team of independent experts, a request was made to modify the use classification of Whitewood Creek from a "cold water permanent fishlife propogation" classification to "cold water marginal fishlife propogation." The new classification would allow survival of catchable size trout but not protect the stream for reproduction. In this case the study concluded that the habitat was limited due to low flows and excessive summer water temperatures. Also achieved was modification of South Dakota water quality regulation to allow for toxicological testing and its use in setting site specific water quality criteria.

MUDDER et al. (1984) describe the Homestake toxicological testing facility located adjacent to the site of the new biological wastewater treatment facility. The primary test

organisms include Daphnia magna, macroinvertibrates (stoneflies and caddisflies), and trout (rainbow and brown).

Dilution water is pumped continuously through the bioassay facility from a pumping station located along Whitewood Creek about one mile above Homestake's discharge. A bioassay facilities manual details the specific protocol employed in the laboratory and is utilized in training technicians, has been prepared by HOMESTAKE MINE (1981).

Capital and operating costs of the toxicological bioassay facility as reported by MUDDER et al. (1984) are shown below.

The two main conclusions drawn from discussion of Homestake's bioassay testwork is firstly that the use of such methods for site specific toxicological testing are most promising. Secondly, the Homestake program demonstrates that industry and regulatory agencies can work together effectively to solve complicated environmental problems.

3. EFFECT OF UNDERGROUND MINING TECHNIQUES ON WATER QUALITY/ METALLURGICAL RECOVERY

HAPTONSTALL (1984) describes the application of vertical crater retreat mining at Homestake's underground workings. This and other mining methods employ diesel and hydraulically powered equipment underground.

Servicing of diesel powered equipment underground is believed to be a potential source of grease, diesel fuel, lubricating oil and hydraulic fluids into the ore.

During a visit to Homestake's CIP plant in September 1984 it was noted that some dark colored oil was floating on top of some CIP adsorption tanks. This oil is likely to result in a reduction in adsorption efficiency of gold onto carbon because oil will coat the carbon with a hydrophobic surface. Pyrite and pyhrrhotite can float on the pulp surface and in some cases looks similar to oil, but several operators from other plants were convinced that the observed material was oil.

This is an example of the need to adopt a systems approach in all mine-mill-tailings systems. Mine operators need to know enough about downstream metallurgical processes that they will be cognizant of practices that could have both negative and positive effects on overall recovery. It is believed that Homestake mining staff are now becoming sensitive to this issue which is a common problem in gold mines all around the world. It is noted that at Homestake the mine has agreed to a 90 day experiment in which no cement will be used in backfill to test what effect this has on effluent treatment. This extent of interdepartmental cooperation is unusual in the industry.

4. DEVELOPING A COOPERATIVE APPROACH TO ENVIRONMENTAL REGULATIONS

A description of the development of the current regulatory limits and background for the huge effort by Homestake into seeking improved technology for cyanide destruction is provided by EDELMAN & WALLINE (1981).

Numerous exhaustive laboratory and pilot tests have been undertaken to find a way to meet the effluent discharge quality limitations that have been imposed.

It is interesting to note that the use of CIP at Homestake's Lead plant stems from their desire to avoid the use of mercury which formerly was used for gold recovery from the slimes fraction of their ore.

Next, a huge, expensive tailings dam was constructed to retain tailings that hitherto were discarded down Whitewood Creek.

The new biological effluent treatment plant is the end result of this cooperative approach.

The effluent limits imposed on Homestake in the 1976 standard shown above is onerous and appears to be arbitrary in some respects. The motivation of setting new regulatory effluent limits on an existing operation without providing the means to meet them is somewhat mystifying and it is hoped that the best interests of the American taxpayer and the nation as a whole are being served by the process of rulemaking that has evolved. Although this report is limited to discussion of technical aspects, the indication of some subsequent flexibility and pragmatism in the development of environmental regulations and the way they are applied is encouraging.

AERO-SURF

process

In 1975, the most significant and cost-effective development in RBC process technology was introduced: the Aero-Surf process.

The Aero-Surf process evolved naturally from efforts to optimize RBC technology. The system offers substantial savings in capital as well as operating and maintenance costs, while enhancing the high treatment efficiency demonstrated by mechanically-driven Bio-Surf equipment.

An Aero-Surf assembly, Figure 1, consists of corrugated media with plastic cups attached around the outer perimeter and over the entire length of the contactor. The media assembly is installed in a tank in the same manner as a conventional unit with the addition of an air header placed below the media. Air is released from the header at a low pressure into the attached cups. The captured air exerts a buoyant force, which in turn exerts a torque on the shaft sufficient for rotation.

Because air cups are not placed over those portions of the media containing radial passage openings, Figure 2, approximately 20% of the released air escapes into the radial passages and flows upward into the corrugated sections. The additional aeration and increased turbulence achieved from this air flow permit a reduction in rotational velocity of the media while achieving an increased degree of treatment. Full-scale Aero-Surf units have been field tested side by side with mechanically-driven units and have demonstrated equal or better treatment efficiency at as little as half the normal rotational speed.

Increased turbulence reduces the biomass thickness, permitting an increased use of Hi-Density media. This results in as much as a 25% reduction in the number of assemblies required for a given application when compared to mechanically-driven units. Figure 3 shows a typical full-scale plant with an air-driven system. A blower delivers air at about 3 psi to a common air header. Approximately 50 to 200 cfm of air is withdrawn through a control valve for each shaft and distributed through the air header beneath the rotating media. Reducing or increasing air flow controls the speed of rotation. Speed of each Aero-Surf unit can be adjusted individually according to changing requirements, providing increased flexibility in the treatment process.

Figure 1. [illegible]

Figure 2. Spacing of air cups on media periphery permits the diffused air to flow through radial passage openings into the media.

Figure 3. In typical Aero-Surf plant, air is piped to individual assemblies from a central blower.

process benefits

Full-scale field testing has demonstrated the process benefits of the Aero-Surf system:

Increased mixed liquor dissolved oxygen concentration is maintained in the Aero-Surf process due to the additional transfer of oxygen by the air diffuser system.

The increased dissolved oxygen level has two biological effects:

1. Maintenance of a completely aerobic biological culture on the media.
2. Increased oxidation-reduction potential (O.R.P.) within the Aero-Surf reactors. The development of undesirable microorganisms is thus reduced; treatment efficiency is increased.

Increased BOD removal. At high loads, or where oxygen-limiting conditions exist, the Aero-Surf process has demonstrated approximately 20% to 50% higher soluble BOD removal than a mechanically-driven RBC system.

Figure 4. Hi-Density media provides 50% increased surface area.

Thinner biomass is achieved with the Aero-Surf process as a result of increased shearing action as air bubbles rise through the radial passages and corrugations in the media. This ability to control biomass thickness is a major advance in fixed-film technology which makes possible more complete optimization of the treatment process. Specifically the thinner biomass:

1. Reduces structural loads on the Aero-Surf shaft assembly.
2. Reduces hydraulic drag of the media, potentially reducing energy consumption.
3. Permits Hi-Density media, Figure 4, to be used at higher BOD concentration. This results in fewer media assemblies which significantly reduces construction and maintenance costs.

Process flexibility through variable speed control optimizes power consumption. The speed of each Aero-Surf assembly can be adjusted to changing wastewater flows and strengths, or effluent requirements.

design features

Aero-Surf media. Standard or Hi-Density Bio-Surf media with polyethylene air cups welded to the periphery captures air released from the air header.

Air Cups. Specially-designed air cups capture air which provides buoyancy to turn the media. Cups are 4 inches deep. Six-inch cups may be used where treatment requirements require increased torque.

Air control valve. Air supply to each Aero-Surf unit is controlled by a butterfly valve which permits variable speed operation.

Air Header. Air moves through the Aero-Surf system through lightweight headers, Figure 6, that run the length of the media assembly and are easily removed for cleaning. **Header mounting brackets** secure header to tank floor.

Air Diffuser. Air is distributed from the header into the air cups and media through coarse bubble air diffusers.

Figure 5. [illegible]

Figure 6. [illegible]

AERO-SURF

operating benefits

Simplicity is the key to Aero-Surf cost-effectiveness, particularly in very large treatment plants employing a substantial number of assemblies.

Maintenance. Many Aero-Surf media assemblies may be driven with a single source of air. Plants may be designed where one 5000 cfm blower can drive up to 50 assemblies. When compared to mechanical drives, the maintenance savings are obvious.

Aero-Surf maintenance manpower savings of up to 90% are not unusual in reports from municipal plants having experience with both air driven and mechanically-driven RBCs.

Optimized energy consumption is made easier by the system's variable speed capability, without the economic disadvantages and maintenance problems of mechanical or electrical variable speed drive systems.

Power factor improvement will further optimize energy consumption when a few large blowers replace a large number of motor-driven mechanical drives.

Operating flexibility. When Aero-Surf units are at less than design flow, during initial start-up years or due to seasonal variations, air flow can be reduced or units taken out of service, thus reducing energy consumption. Under the same low flow conditions, activated sludge and oxidation ditch systems usually require full power to maintain adequate mixing.

When an Aero-Surf system is operated at higher than design flows (due to temporary industrial discharge, for example), air to the units can be increased to maximize BOD removal and maintain control over biofilm conditions.

Provision for stand-by. Stand-by blower capability in an Aero-Surf system in effect provides a stand-by drive for each Aero-Surf unit. A back-up system is not economically feasible in mechanically-driven RBC plants.

Stand-by power generation capability in an Aero-Surf plant need only be sufficient to operate a single blower. All units can then operate at minimum speed until full power is restored. Since mechanically-driven RBC units operate at fixed speeds, stand-by power must duplicate full power demand.

Ventilation of buildings or enclosures is required in some applications. The air rates provided by Aero-Surf system blowers reduce, or even eliminate, the need for separate ventilation fans.

Operator safety is improved. Blower maintenance is performed away from the RBCs and does not expose personnel to chains, belts, gears, etc. In many Aero-Surf installations, all maintenance can be performed outside the RBC enclosures.

Figure 8. RBC speed and resulting dissolved oxygen profile, Aero-Surf vs. mechanically-driven systems.

process development

Extensive full-scale Aero-Surf process field testing has been performed at Milwaukee's South Shore wastewater treatment plant, Figure 7. A research and development facility, equipped with Aero-Surf and Bio-Surf process assemblies, has served as the basis for defining Aero-Surf process advantages.

As a result of research, a significant body of information on BOD removal, nitrification and sludge characteristics has been produced.

The data in Figures 8, 9, and 10 were developed from the full-scale tests conducted at the South Shore plant.

Biological Treatment of Cyanidation Waste Waters

T.I. Mudder and J.L. Whitlock

Abstract—*An attached growth aerobic biological treatment process has been developed at Homestake Mining Co.'s Lead operation which not only oxidizes free and complexed cyanides, including the stable iron complexed cyanides, but also thiocyanate, and the oxidation byproduct ammonia. Through the employment of a mutant strain of bacteria which has been gradually and specifically acclimated to the waste, these potential pollutants are mineralized to relatively harmless sulfates, carbonates, and nitrates. The resultant effluent, through toxicological testing, has been shown compatible with the receiving stream, which serves as a cold water marginal trout fishery.*

Introduction

Metal complexed cyanides in waste waters form as a result of interactions of free cyanide with metals present in the waste water and exhibit varying degrees of stability, toxicity, and treatability. Thiocyanate, a pollutant commonly found in cyanide-bearing waste waters, is formed through the interaction of free cyanide with sulfur containing species (i.e., pyrrhotite) both present in process and waste waters.

In certain industrial processes, such as the beneficiation of gold and silver, cyanide is an essential reagent. Since free cyanide, complexed cyanides, and thiocyanate are potentially toxic to humans and aquatic organisms, these compounds must be removed from waste waters prior to their discharge into surface or ground waters serving as potential potable water sources, marine or fresh water habitats.

Since 1977, personnel at Homestake Mining Co.'s Homestake gold mine in Lead, SD, have been engaged in research and development of a process to treat a maximum of 21,000 m^3d (5.5 million gpd) of combined mine and tailings impoundment waste waters (Table 1). The mine water is pumped continuously from underground and originates from several process and natural sources. The tailings impoundment waste water or decant water is separated from the tailings in a containment dam and flows to the treatment facility through pumping or by gravity. The treated waste water must be of high quality as it is discharged into Whitewood Creek, which serves as a cold water marginal trout fishery stocked seasonally with catchable-size brown trout.

Table 1—Chemical Characteristics of Combined Mine and Decant Waste Waters

Parameter	Value*
Thiocyanate	45.0-75.0
Total cyanide	0.50-10.00
Method-c cyanide	0.50-5.00
Iron	0.50-2.00
Copper	0.10-1.50
Nickel	0.10-.50
Zinc	0.10-.50
Ammonia-N	1.0-8.5
Phosphorous-P	trace
pH	5.5-10.0
Temperature (°C)	10-25

*All values in milligrams per liter except temperature and pH.

Various chemical and/or physical treatment processes were pilot plant tested and the effluents evaluated on both a numerical and toxicological basis in a flow-through bioassay facility to ensure effluent compatability with the receiving stream. However, construction of a treatment facility based upon chemical and/or physical processes never materialized due either to inadequate treatment performance, residual toxicological effects associated with the effluent, or prohibitive capital and/or operating costs.

As a result, beginning in early 1981, biological treatment was examined and evaluated on a pilot plant scale, yielding a simple cost effective process, the performance of which equaled or exceeded that of all other processes evaluated, while producing an environmentally compatible effluent. Actual construction of the facility was initiated in February 1983 with plant start up scheduled for the summer of 1984. The treatment plant design incorporated the use of flow equalization, 48 low- and high-density rotating biological contactors, and chemical addition for growth supplementation and residual metals/solids removal, secondary clarification, and pressure sand filtration (dual media).

SME preprint 84-37, SME-AIME Annual Meeting, Los Angeles, CA, Feb. 1984. MMP paper 84-607. Manuscript Nov. 1983. Discussion of this paper must be submitted, in duplicate, prior to Oct. 31, 1984.

Analytical and Toxicological Testing

Comparison and evaluation of the various treatment processes required accurate and interference free analytical procedures. Concurrently with the pilot plant testing of the chemical and physical treatment processes, research was conducted to evaluate and develop reliable methods for cyanide analysis. Two analytical methods with modification were found dependable and were used extensively in the laboratory during pilot plant evaluations. The modified ASTM procedures included the total cyanide reflux, substituting phosphoric acid for sulfuric acid, and the method-c cyanide reflux utilizing acetic acid, both methods allowing accurate and precise measurement of low levels of cyanide (0.02 mg/L ± 0.01 mg/L). The total cyanide reflux measured free and metal complexed cyanide, including cyanide bound to iron. The method-c cyanide measurement, considered the toxicologically significant cyanides, included free and metal complexed cyanides (i.e., copper, nickel, and zinc cyanides), except cyanide bound to iron. The biologically treated waste water provided additional accuracy and reliability in its analysis as potentially interfering substances were removed during treatment (i.e., thiocyanate) or were not required for treatment (i.e., chlorine, sulfur dioxide, copper, or hydrogen peroxide).

However, emphasis on specific parameter removal could have resulted in toxic effluents due to pollutants associated with or produced through breakdown of target pollutants that were not analyzed for and/or removed through further treatment. As a result, a toxicological testing facility was constructed with a twofold purpose. First to determine and compare the toxicological effects of the various treatment processes tested and second to utilize the data in the eventual development of site specific effluent discharge criteria. The organisms tested in acute (96 hr) and chronic long-term (greater than 21 days) flow-through bioassays included 5.1 cm (2 in.) fingerling rainbow trout and 15.2 cm (6 in.) stockable-size brown trout obtained from the local state fish hatchery. Other organisms tested in acute and long-term flow-through bioassays included the macroinvertebrates, stone flies, mayflies, and caddis flies. These organisms serve as the primary food source for the stocked trout populations, and therefore must be protected environmentally.

In addition, rapid measurement of relative process effluent toxicities was obtained with 48-hour static bioassays utilizing the microinvertebrate, *Daphnia magna*.

Evaluation of Chemical and Physical Treatment Processes

Several chemical and physical treatment processes were pilot plant evaluated either alone or in combination (Table 2). These processes included acidification/volatilization, ozonation, ion exchange, Prussian blue oxidation/precipitation, carbon adsorption, alkaline chlorination, and copper catalyzed hydrogen peroxide (DuPont Kastone process). The Inco sulfur dioxide oxidation/precipitation process was not pilot plant evaluated as estimates of chemical usage and sludge handling rendered the process cost prohibitive and impractical for this application. Prior to biological treatment, the pilot plant testing program indicated the Kastone process provided the best solution to Homestake's treatment problem, based upon numerical and toxicological evaluations. The patented copper catalyzed hydrogen peroxide process removed free and metal complexed cyanides, including the stable iron complexed cyanides, but it did not remove thiocyanate, the oxidation byproduct ammonia, or residual copper, all of which were potential toxicants requiring additional treatment for their removal. The process required large quantities of expensive chemicals resulting in expected high operating costs.

As a result, research was directed toward evaluation and development of a biological treatment that was theoretically capable of overcoming the limitations associated with other treatment processes, while producing a high-quality, low-toxicity effluent simply and cost effectively.

Development of the Biological Treatment Process

Although full-scale biodegradation of cyanidation waste water was not practiced in the mining industry, the literature indicated biological oxidation of free cyanide, metal complexed cyanides, thiocyanate, and their breakdown products was possible on a laboratory scale (Howe, 1965; Knowles, 1976; Murphy and Nesbitt, 1964; Pettet and Mills, 1954; Rael et al., 1977).

To test the effectiveness of biological treatment both suspended growth and attached growth processes were evaluated with and without supplemental carbon sources (raw sewage). The results indicated supplemental carbon sources were not required for the biological degradation of cyanide complexes and thiocyanate as these compounds themselves served as the sole carbon source for the bacteria. The biological processes tested included activated sludge, a suspended growth process, and several attached growth processes including trickling filters (rock and plastic media), biological towers, aerated biological filters (Eimco BAF process), and rotating biological contactors (RBCs) (Table 3).

The bacterial seed was obtained from several sources on Homestake property and was found indigenous to Homestake waste waters. During the pilot plant evaluations the bacteria were gradually and specifically acclimated to the waste water combination (mine/decant) to be treated. Although microbial seed was obtained from the local sewage treatment plant (activated sludge) to aid in inoculation of the various biological pilot units along with Homestake microbial seed, microbial characterization of the local sewage treatment plant (STP) activated sludge indicated the bacteria responsible for cyanide degradation were not present. Therefore, the use of microbial seed from the local STP was discontinued.

The only chemical requirements were an inorganic carbon source to aid nitrification (i.e., soda ash) and phosphorous as a trace nutrient (i.e., H_3PO_4). The biological treatment processes removed through oxidation and adsorption thiocyanate, free and metal complexed cyanides (including iron complexed cyanides), metals (principally copper), and ammonia, a byproduct of thiocyanate and cyanide degradation. The products of biological degradation included the relatively harmless anions sulfate, nitrate, and carbonate. The kinetics of thiocyanate, cyanide, and ammonia oxidation were generally zero order to levels of 1 mg/L for thiocyanate and cyanide, and 4-5 mg/L for ammonia. Below these levels the reaction kinetics shift to higher orders as substrate concentrations become limiting.

The activated sludge exhibited the highest degree of treatment efficiency with regards to total and method-c cyanide removal. However, due to slow microbial growth evidenced by long sludge ages (20 to 40 days) coupled with

accumulation of toxic metals within the biomass, the system failed at 60 days. Modification of the process to include pretreatment for metals removal would be required to yield a viable process, but was not tested as it was considered cost prohibitive and impractical in this application.

In general, all the attached growth processes mentioned yielded good to high-quality, low-toxicity effluents, but the RBC's superior performance coupled with its cost-effective design and low operating costs made it the process of choice for incorporation into the overall treatment plant design.

Biological Treatment Facility

In Figure 1 a schematic of the proposed biological treatment facility presently under construction is presented. Integral to the overall design was development of a steady flow system which allows precise control of the mine and tailings impoundment waste water flows and ratios. The ratio of the two waste waters is varied throughout the year and controlled either manually or automatically with the use of an on-line thiocyanate monitor developed by Homestake specifically for this application.

The rotating biological contactor design incorporated the use of low-density media in the first and second stages for thiocyanate and cyanide removal, and high-density media in the remaining stages for nitrification. To minimize structural problems and maximize process flexibility, several features were incorporated into the design. First, additional shafts were placed in the first and second stages to provide additional surface area to reduce biofilm thickness and biomass weight. Secondly, the fiberglass baffles between stages are removable, allowing plug flow or complete mix operation of the process. Thirdly, reversible variable speed drives were included on all RBC shafts. Lastly, supplemental air was made available to all stages to assure adequate dissolved oxygen and to provide for biomass stripping. The biomass weight was to be monitored with the aid of temperature-compensated electronic load cells with continuous readout capabilities. The RBCs are individually housed in insulated fiberglass covers.

Following the RBCs, ferric chloride and/or polymer can be added prior to secondary clarification to aid in residual metals and solids removal. The clarifier was constructed of concrete and was covered with a fiberglass dome. The clarifier underflow containing the settled solids was to be either discharged to the tailings impoundment or processed for metals recovery. Prior to discharge the waste water passes through three existing pressure sand filters which were retrofitted with dual media (sand and anthracite). The total hydraulic residence time through the RBCs, clarifier, and filters would be approximately five hours at 21,000 m^3/d (5.5 million gpd).

Fig. 1—Schematic of the biological treatment plant

Table 2 — Summary of Chemical/Physical Treatment Processes

Treatment Process	Summary of Parameter Removal					Comment
	Thiocyanate	Total Cyanide	Method-C Cyanide	Ammonia	Metals	
Ozonation	yes	no	yes	—	no	The pilot plant consisted of two 152-mm- (6-in.-) diam 5.5-mm (18-ft) plexiglass columns packed with 16-mm- (5/8-in.-) diam Pall rings. The columns were operated in series with the pilot plant flow, pH, and reaction time being 0.19 L/s (3.0 gpm), 8.0, and 2.5 hr, respectively. Excessive ozone demand if SCN is present (2.8gO_3/gCN^- and 4.2gO_3/g SCN^-). A staged sealed reactor with off-gas recycle would be required along with staged O_3 injection due to its low solubility. High capital and O/M costs if SCN^- is present as it is oxidized in preference to CN^-. Also a high level of operator expertise is required.
Acidification/ volatilization	—	yes	yes	no	no	The pilot plant consisted of a three-cell Denver flotation unit with the cells operated in series to achieve a 4.0-hr residence time at 0.05 L/s &0.80 gpm). The pH, air flow rates, and acid consumption were 3.0-4.0, 0.071 m^3/s (150 scfm), and 100 mg/L (0.0008 lb per gal) of H_2SO_4, respectively. Excessive air, power, acid, and base requirements rendered the process cost prohibitive.
Carbon adsorption	no	no	yes	—	no	The pilot plant consisted of two 152-mm- (6-in.-) diam plexiglass columns 2.4 m (8 ft) in length packed with 1.5 m (5 ft) of 12 mesh Westates GAC carbon. The two columns were operated in series of flow rates varying from 1.4-3.4 L/m^2/s (2-5 gpm/ft^2). SCN^-, total cyanide, and metals broke through quickly. Significant removal of method-c cyanide was realized. The carbon adsorption process was examined primarily as a polishing process for the biological treatment process. Regeneration of the carbon was not examined. Initial capital costs and projected operating costs were prohibitive.
Ion exchange	no	yes	yes	—	yes	The pilot plant consisted of 152-mm- (6-in.-) diam plexiglass columns 3.0 m (10 ft) in length containing a resin dept of 0.9-1.5 m (3-5 ft). The resins tested were all of the strong base type, such as A-101-D, as the metal cyanide complexes were negatively charged. An 8% NaOH solution was employed for backwash for 45 min at 3.4 L/m^2/s (5 gpm/ft^2). SCN^- breaks through quickly, irreversibly poisoning the resins. Ion exchange should be used only when SCN^- is not present and provides an acceptable polishing process in its absence. Other resins tested include A-102 and A-109. Flow rates of 1.4-3.4 L/m^2/s (2-5 gpm/ft^2) were examined. A-7 was also examined but lost its exchange capacity following successive regeneration.
Alkaline chlorination	yes	no	yes	yes	yes	The pilot plant consisted of three 200 L (55 gal) Nalgene barrels operated in series to produce a chlorine contact period of 45 min. The pilot plant flow was 0.19 L/s (3.0 gpm). Bleach was employed as the chlorine source and caustic was used for pH control (10.5-11.0). Following the oxidation sequence was clarification with polymer addition and pressure sand filtration. Sulfite and CO_2 were employed for residual Cl_2 destruction and pH adjustment, respectively. Ammonia could be destroyed if breakpoint Cl_2 was used. Excessive Cl demand if SCN^- is present (4.9gCl_2/g SCN^- and 2.8gCl_2/gCN^-). Process most viable for SCN^- and iron cyanide free waste waters.
Copper catalyzed hydrogen peroxide with ferric chloride addition for residual metals removal	no	yes	yes	no	yes	The pilot plant consisted of several 200 L (55 gal) Nalgene barrels operated in series to achieve a 2.5-hr contact period. The pilot plant flow rates varied from 0.13 to 0.20 L/s (2.0-3.0 gpm). 100 mg/L of H_2O_2, 10 mg/L of Cu, and 20.0 mg/L of $FeCl_3$ were employed. The pH was maintained at 9.0 with either caustic or lime. The process was operated at ambient temperatures. Following the oxidation sequence was a clarification step followed by pressure sand filtration. Excessive chemical requirements and costs rendered the process cost prohibitive for this application.

Table 3 — Summary of Biological Treatment Processes*

Parameter	Thiocyanate	Total Cyanide	Method-C Cyanide	Ammonia	Copper	Comment
Pilot plant influent	60.0 ± 10.0	6.50 ± 2.10	4.10 ± 1.30	6.0 ± 1.0	1.00 ± 0.40	The pilot plant influent is varied throughout the year from a ratio of 7/30 mine/decant (tailings impoundment) waste water in winter to 50/50 mine/decant waste water ratio in the summer. The pollutant concentrations are highest in the winter with temperatures falling to 10°C in the waste water.
2.0-m RBC pilot plant effluent	1.0	0.35 ± 0.10	0.05 ± 0.02	0.50	0.06 ± 0.02	The pilot plants were furnished by Envirex. The original feasibility study was undertaken with the use of a 0.5-m RBC pilot plant. The 2.0-m pilot plant was operated with the first and second stages unbaffled. Supplemental aeration was fed to each stage of the pilot plant at an equivalent rate of 0.07 m^3/s (150 scfm). Stripping of biomass required 0.283 m^3/s (600 scfm). The total surface area of the pilot plant was 743 m^2 (8000 ft^2). The pilot plant was operated at flow rates of 0.13-0.50 L/s (2.0-8.0 gpm). Effluent values recorded in this table were obtained on clarified and sand filtered effluent. The rate controlling oxidation in the overall design was nitrification.
Laboratory bench scale activated sludge	1.0	0.27 ± 0.27	0.06 ± 0.06	—	0.35 ± 0.12	The bench scale reactors consisted of 5-L (1.3-gal) plexiglass cylinders operated on a 24-hr draw and fill cycle. Sludge ages examined ranged from 10 to 40 days. Activated sludge from the local sewage treatment plant was utilized for the initial biomass along with microbial seed from Homestake sources. Eventually aeration periods from 2 to 24 hrs were examined. The system failed at 60 days due to metals accumulation and toxicity.
22-ft biotower	1.0	0.87 ± 0.30	0.08 ± 0.04	—	0.10 ± 0.04	The pilot plant consisted of a 0.6-m- (2-ft-) diam steel pipe 6.8 m (22 ft) in height packed with KORO-Z plastic media supplied by B.F. Goodrich Co. Maximum flow rate achieved was 0.17 L/m^2/s (0.25 gpm/ft^2) with 0.17 L/m^2/s (0.25 gpm/ft^2) recycle flow. Supplemental air was provided countercurrent to the gravity waste water flow. Nitrification data is not meaningful as soda ash was not added to the raw waste water feeding into the biotower. Trickling filters were also examined. The pilot plants consisted of two 1.8-m-/0.15-m-diam (6-ft-/6-in.-diam) plexiglass columns operated in series of flow rates similar to those of the biotower. The trickling filters were either packed with 16-mm- (5/8-in.-) diam Pall rings or crushed rock 13 mm (1/2 in.) in diam. The performance of the trickling filters was slightly less than the biotower.
Biological aerated filter (BAF process)	1.0	1.00 ± 0.60	0.06 ± 0.02	1.2 ± 0.7	0.03 ± 0.03	The pilot plant was supplied by Elmco. The pilot plant consisted of two 0.30-m- (1-ft-) diam plexiglass columns operated in series containing 1.8 m (6 ft) of their patented media. The columns were operated in parallel and in series. The data presented in this table was from the series operation. Hydraulic flow rates were varied from 0.27 to 1.0 L/m^2/s (0.40-1.50 gpm/ft^2). Supplemental aeration was added countercurrent to the gravity waste water flow.

**All values in milligrams per liter.*

Future Research and Development

Present research is directed at elucidation of the specific reaction orders and rates of thiocyanate, free cyanide, and metal complexed cyanide degradation. In addition, further research is required to determine the maximum levels of thiocyanate and cyanide degradation possible. Also, research continues to examine additional biological (algae) and chemical (ferric salts) treatment processes to aid in removal of residual copper in the effluent.

Toxicological testing continues with emphasis on developing site-specific discharge criteria and elucidation of the relationship of light intensity to the breakdown of iron complexed cyanides.

The full-scale facility will be in operation by August 1984, with two patents being received by the authors on behalf of Homestake covering the specific bacteria responsible for the thiocyanate and cyanide degradations and its use in the accompanying process. ■

INTRODUCTION

The McLaughlin project is interesting in several respects:

1. It is the most expensive gold mine to be installed in North America to date, and the first to use pressure oxidation to treat refractory gold ore.

2. It is located in California in a high profile area above Lake Berryessa, overlapping three counties with different environmental regulations. The operating permits are more comprehensive than most.

3. Pressure oxidation will be used to treat the ore ahead of cyanidation, to liberate gold from an ore containing pyrite and sulfosalts.

4. A total of more than 280 permits had to be applied for in order to bring this project into operation.

From a water management standpoint there are several interesting features:

5. During the pressure oxidation step numerous metals are brought into acid solution. The pre-oxidized pulp is washed in two 55' Ø Enviroclear thickeners (6:1 wash ratio) ahead of leaching to remove as much of the dissolved metals and acid which are precipitated and neutralized using feed to the autoclaves which has a high carbonate level. Thereafter the separated solution is to be neutralized with lime to precipitate $Fe(OH)_3$ and $Mg(OH)_2$ as well as the metals that precipitate at higher pH. This will require 150-200 tpd lime depending on the amount of sulfide in the ore.

   Removal of the metals ahead of cyanidation reduces cyanide consumption and results in lower complex cyanides reaching the tailings pond.

   A general arrangement of the mine, mill, tailings, wasterock and metallurgical process is shown in the attached diagram from KUNTER et al. (1984).

6. As a result of autoclave oxidation, generally silver recovery in the subsequent cyanidation step will be poor as silver, along with heavy metals become tied up in jarosites. Modification of the pressure oxidation conditions is reported to improve silver recovery significantly (BULL et al. 1984; and WEIR, 1985), but raises new questions about the ultimate disposition of other metals in the circuit and tailings.

7. Tailings will be disposed of using a layered sub-aerial method similar to that used in South Africa and at Key Lake Mining in Saskatchewan. The tailings pond has a naturally impermeable clay base and will have a large gently sloping beach area and a large evaporation pond.

8. Because sulfides in the tailings have mostly been oxidized in the autoclave preoxidation step, the tailings will have a low sulfide content that one day could become a source of acid mine drainage. In this way McLaughlin will avoid the threat of serious future acid mine drainage problems.

9. Wasterock disposal sites will not be required to be lined because of the managed method in which the waste is disposed of.

10. The decision to proceed with this $250 million project was made at a time when gold prices were significantly higher than they are today. Ultimate process parameters and performance data as well as the economics of this fine new gold recovery

operation will be significant to many current projects under evaluation around the world that anticipate using pressure oxidation ahead of cyanidation.

11. Seldom, perhaps never, has a mining company gone to such lengths to make a mine-mill-tailings complex compatible with the environment and the community. This operation will hopefully be the one that swings public opinion around to favor responsible mining operations in their midst. The McLaughlin project is located at the site of an old mercury mine which did disfigure the landscape many years ago. Homestake will take this opportunity to leave the area in better condition than they found it.

12. The McLaughlin project is to be operated as a zero discharge site which is possible because of its net evaporation climate. Nonetheless careful water balance modelling on an annual and seasonal basis has been necessary. The generalized network flow computer model called Modsim used for the purpose was described by FERGUSON et al (1983).

13. The McLaughlin operation represents the current state of the art in mine-mill-tailings design from an environment protection standpoint.

LOCATION	Knoxville, California about 80 miles northeast of San Francisco, just north of Lake Berryessa.
CAPACITY	Mill 3000 stpd
STARTUP	June 1985 (projected)
STRIP RATIO	5 to 5½ : 1 Ultimately the pit will be 1 mile long, 0.5 miles wide and 700 feet deep.
ORE GRADE	20 million tons at 0.16 oz/t. Actual grade varies considerably as there are high grade ore zones.

ORE TYPE

The epithermal ore occurs in a major thrust zone. The orebody is complex and contains twelve distinct ore types nearly all with complex mineralogy which render the ore refractory. Gold is disseminated and fine grained (about 20 micron mean gold particle size), associated with fine grained sulfide minerals.

Sulfides are mainly pyrite, with minor marcasite, chalcopyrite, sphalerite and cinnabar. Gold occurs typically as gold silver electrum associated primarily with silver antimony sulfosalts, miargyrite, pyraginite, freibergite and polybasite, and also occurs locked in gangue.

Just about every base metal in the periodic table is associated with this ore including 1 oz Hg per ton ore.

The gold is refractory for three main reasons reported by KUNTER (1984).

1) Encapsulation in sulfides and sulfosalts.
2) Pressence of preg-robbing carbonaceous and clay materials.
3) Surface coatings of jarosite and hematite on weathered ore.

PROCESS SELECTED

The selected process according to KUNTER et al. (1984) and GUINIVERE (1984) is as follows:

- Contact the ore with acid to reduce $CO_3^{=}$ content
- Pressure oxidation in autoclave at 160-180°C
- Washing to remove soluble metals
- Cyanidation to leach gold
- CIP Gold recovery
- Sub-aerial tailings disposal

KUNTER et al. (1984) report the following conditions for the autoclave reaction:

Pressure	1300 kPa (188psig)
Temperature	160-180°C
Retention Time	1.5 - 2 hours
Pulp density	40 - 45%
Final Acidity	15 - 20 g/l H_2SO_4
Final emf	420 milliwatts (SCE)

The above conditions achieve oxidation of at least 90% of the sulfides present which is necessary to make the gold amenable to cyanidation. However, more than 92% of the silver and iron was found to report to the fines fraction of the oxidation residue which suggests that the silver is lost as an argentojarosite.

OPERATING COST

Estimated "cash costs" of around $240/oz. Autoclave preoxidation approximately doubles the operating cost to $25-35/t range.

RECOVERY

Recoveries of about 95% are indicated when the above process is used compared with direct cyanidation recoveries varying form 5% to 80% depending on the percentage of gold locked in the sulfides and the presence of carbonaceous materials, clays and surface coatings. Average recovery without oxidation is around 45%.

METALLURGICAL TESTING

The test and development results that went into the selection of pressure oxidation ahead of cyanide leaching are described by KUNTER et al. (1984).

Roasting and cyanidation of calcines was rejected because the ore contains mercury and insufficient sulfur for acid production. Flotation, roasting and calcine leaching results in lower recoveries.

Several other processes were tested and rejected on the grounds of inadequate recoveries:

- direct cyanidation
- direct leaching with non-cyanide reagents
- chemical oxidation by chlorine, ferric chloride, thiosulfate and sodium sulfide.

None of the above achieved a satisfactory recovery - invariably 0.05 Au/t or more was left in the leach residue solids.

ENVIRONMENTAL PERMITTING

The operation area is spread out over a 25 mile long project site which overlaps Yolo, Lake and Napa Counties, each of which has a different set of regulations. Napa County also falls in the Bay Area Air Quality District. Napa County became the lead county and was made responsible for data collection for the EIR. An environmental data aquisition committee was formed which involved Homestake Mining Comapny and 28 specialty subcontractors to gather environmental data. Homestake elected to proceed with development of the project in July 1982 and filed a draft EIR in August 1982 three years from the first step in evaluating the project. Preliminary permits were granted in September 1983 and construction commenced immediately. More than 285 permits were required and decisions were needed on 40 options. Under the regulations it is not

FIGURE 4

MILL PROCESS FLOWCHART WITH GENERAL PROJECT PERSPECTIVE

permissible even to store equipment on site that make dust until the Bay Area Air Quality permit has been granted. The new mine-mill operation required 13 million yd^3 earthwork and construction of a 6000 acre ft reservoir on site with 120 ft high wall and 1 million yd^3 earthworks.

Environmental problems encountered were overcome as follows:

1. Tailings pond was required to be zero discharge. The site selected for tailings disposal has a naturally low permeability of less than 10^{-7} cm/sec.

2. The tailings pond is installed down grade from the processing area so all spills will end up in the tailings pond.

3. Wasterock will be disposed of close to the mine on top of serpentenites. Drainage from the area is to Hunting Creek and ultimately to Lake Berryessa. Extensive cut-off trenches, rock drains and settlement ponds have been constructed to prevent pollution of the Berryessa system.

   Sulfide containing wasterock to be surrounded by high lime containing wasterock to neutralize any acid mine drainage generated.

4. Low grade ore stockpiles and waste liquor are placed over 10 ft wide 5 ft deep underdrains to collect seepage from both the low grade ore stockpiles and wasterock disposal site.

5. A study comparing haul vs. conveyors vs. pipeline conveying of crushed ore to the process area led to selection of pipeline transfer as being the most environmentally favorable.

Homestake Mining Company's Environmental Control Department supervised the permitting process with significant help from several carefully selected contractors:

EIS and Baseline studies:	D'Appolonia & Associates, now IT Corporation 17500 Red Hill Avenue Irvine, CA 92714 Telephone (714) 261-6441 Contact Ed Sirota
Air Quality Permits:	ERT Corporation
Socio-Economics:	Dames & Moore

Permitting, and quality assurance on all aspects of the project that could impact the environment from a water standpoint, including the water supply reservoir, wasterock disposal, tailings impoundment (including design), water balance management, runoff water collection and control were provided by:

Steffen Robertson & Kirsten
7510 West Mississippi Ave. # 210
Lakewood, CO 80226

Telephone (303) 936-8254
Contact Dr. Ian P. G. Hutchison
Dr. Phil DeDycker

COST OF ENVIRONMENTAL CONTROL MEASURES

The environmental impact report and data gathering backup cost $6 million. Dams for sediment control in runoff water cost $5 million. Overall $11 million has been spent on special design features for dust collection and water runoff control during construction and operation.

Just the quality assurance program for the water supply reservoir, wasterock disposal, tailings impoundment, water balance management and runoff collection and control, and associated permits cost around $2 million.

PERMITS

Of the 231 permits required to bring the McLaughlin project into production Randol International Ltd. found two of particular relevance to water management. These were the tentative California Regional Water Quality Control Board, Central Valley Region order for Waste Discharge Requirements, and the Federal NPDES Permit which is also administered by the California Regional Water Quality Control Board - Central Valley Region. Of these two permits, the NPDES permit is the shortest and simplest. It is inserted below to provide an idea of the kind of monitoring and reporting that is required for this operation in California.

OPERATOR TRAINING

An important aspect of water management, and environmental control is operator awareness and training. Homestake has established a training school on the property. Of the roughly 1200 people involved in the construction phase, about 250 will be kept on to operate the mine and the plant.

Detailed models of the complete project have been constructed as a design, construction and training aid. A computer model of the oxidation process provides input to an operator interface unit of the Bailey System 90 DCS to simulate this area for operator training.

CALIFORNIA REGIONAL WATER QUALITY CONTROL BOARD
CENTRAL VALLEY REGION

ORDER NO. _____

NPDES NO. CA0081477

WASTE DISCHARGE REQUIREMENTS
FOR
McLAUGHLIN MINE
HOMESTAKE MINING COMPANY
AND
US BUREAU OF LAND MANAGEMENT
YOLO, LAKE AND NAPA COUNTIES

The California Regional Water Quality Control Board, Central Valley Region (hereafter Board), finds that:

1. Homestake Mining Company (hereafter Discharger) submitted a report of waste discharge, dated 15 April 1983, to discharge waste under the National Pollutant Discharge Elimination System.

2. The proposed mining operation will operate in part on public lands administered by the US Bureau of Land Management (hereafter Discharger).

3. The Discharger proposed to discharge water in contact with mine activities from five sedimentation ponds into Hunting Creek and Knoxville Creek, both tributary to Lake Berryessa, a water of the United States.

4. Homestake Mining Company proposes to develop a gold mine and mineral extraction facility (mill) to process about 4000 tons of ore per day. Units of the mine include: mine pit, waste rock site, grinding and crushing area, mill, low grade ore storage, slurry line, tailings disposal facility, water supply reservoir, interconnecting roadways and electrical transmission corridor.

5. The mining process will begin at an open pit mine which will ultimately be one mile long, one-half mile wide and 400 feet deep. Higher grade ore bearing rock will be crushed, ground and piped through a 4-1/2 mile slurry pipeline to the mill site. Waste rock from the mine pit will be disposed of on 342 acres some of which are public lands administered by the US Bureau of Land Management. The pipeline slurry will undergo a cyanide leach process to extract gold at the 35 acre mill site. Processed slurry will be discharged to the 546 acre tailings disposal facility.

6. The discharge to land of all mining activities, including the tailing disposal reservoir, is regulated through separate waste discharge requirements.

7. The report of waste discharge describes the water discharge as follows:

Pond	Discharge Point Serial Number	Description
T_1	001	Sediment trap for topsoil stockpile taken from the tailings reservoir. T_1 will function primarily during the first three years before the topsoil is revegetated and again towards the end of project during the reclamation phase. During most of the operating life of the project, the sediment yield to the pond is expected to be minimal. The pond will be maintained for the entire project and reclamation period.
T_2	002	Same as pond T_1.
W_1	003	Sediment trap for the waste rock disposal facility from stormwater runoff and waste rock subdrainage. This pond will be required for the life of the project.
W_2	- -	Sediment trap within the waste rock disposal facility. This pond may or may not be required. If constructed, it would flow only into pond W_1, and therefore would not be an NPDES discharge point.
M_1	004	Sediment trap for the grinding facility area during the mine construction period only (i.e., the first 1 to 2 years). Thereafter, the pond will be used as a water-recycling pond and will not be an NPDES discharge point.
M_2	005	Sediment trap for the early years of development at the south pit. This pond will be required for approximately the first 7 years of mining. Thereafter, all runoff from pit disturbance will be contained within the pit and the pond decommissioned.

8. The Board, on 25 July 1975, adopted a Water Quality Control Plan for the Sacramento River Basin (5A). These requirements are consistent with the Plan.

9. The beneficial uses of Lake Berryessa are municipal, industrial, and agricultural supply; recreation; esthetic enjoyment; navigation; ground water recharge; fresh water replenishment; hydroelectric power generation; and preservation and enhancement of fish, wildlife and other aquatic resources.

10. The beneficial uses of the ground water downstream of the project are municipal and agricultural supply.

11. The chemical quality of the ground and surface waters in the immediate vicinity of the tailings disposal facility and the waste rock disposal facility is generally poor, when compared to EPA Primary and Secondary Drinking Water Standards. Boron levels frequently exceed the recommended levels for continuous irrigation use.

12. Effluent limitation standards established pursuant to Sections 301, 302, and 304 of the Federal Water Pollution Contol Act and amendments thereto are applicable to the discharge.

13. On 6 July 1983, the Napa County Planning Commission certified the final Environmental Impact Report/Environmental Impact Statement (EIR/EIS) for the Homestake Mining Company McLaughlin Gold Project in accordance with the California Environmental Quality Act (CEQA) Public Resources Code Sections 21000, et seq. The EIR/EIS discloses that the project may have the following significant impacts on water quality:

    a. Increased erosion during construction.

    b. Landslides along the perimeter of the water reservoirs.

    c. Increased sedimentation to streams during construction.

    d. Increased TDS and heavy metals concentration to Hunting Creek downstream of the waste rock dump.

    e. Contamination of Hunting Creek from accidental spills of mill reagents or tailings disposal facility rupture.

14. The Board has reviewed the EIR/EIS. These waste discharge requirements provide protection to water quality equal to or more effective than the mitigation measures in the EIR/EIS relating to water quality. Compliance with these waste discharge requirements will mitigate or avoid the following significant impacts on water quality listed in Finding 13:

    a. Landslides along the perimeter of the water reservoir. Mitigation of this potential impact is required by turbidity, sedimentation and erosion controls contained in these requirements.

    b. Increased TDS and heavy metals concentration to Hunting Creek downstream of the waste rock dump. Mitigation of this potential impact is accomplished by receiving water limitations on heavy metals and the requirement to implement best available technology (BAT) to limit mineralization.

15. The following impacts will be mitigated to some extent by these requirements, but the EIR/EIS identifies these as unavoidable potentially significant environmental impacts:

    a. Increased erosion during construction.

b. Increased sedimentation to streams during construction.

c. Contamination of Hunting Creek from accidental spills of mill reagents or tailings disposal facility rupture.

While these significant detrimental impacts may occur, the Board finds these impacts are outweighed by the potential benefits of the project. This decision is based on the two potential benefits to water quality listed in the EIR/EIS:

a. Long-term improvement to Knoxville Creek water quality downstream of mine pit due to the ultimate elimination of poor quality runoff from the mine pit area.

b. Long-term reduction in sedimentation to Davis Creek downstream of the reservoir through dam releases of better-quality water than that presently existing.

16. Subsequent to the preparation of the final EIR/EIS, Discharger and the Solano Irrigation District (SID) entered into an Agreement (the SID Agreement) which provides for a comprehensive monitoring program and a series of response mechanisms designed to preclude any potential adverse environmental impacts on water quality which might otherwise occur in connection with the project. Pursuant to the SID Agreement, Discharger has agreed to comply with specified requirements in order to assure nondegradation of the water quality of any surface or subsurface waters flowing or draining into or through Hunting, Soda, Knoxville, Putah or Eticuera Creeks into Lake Berryessa.

17. The Board has notified the Discharger and interested agencies and persons of its intent to prescribe waste discharge requirements for this discharge and has provided them with an opportunity for a public hearing and an opportunity to submit their written views and recommendations.

18. The Board, in a public meeting, heard and considered all comments pertaining to the discharge.

19. This Order shall serve as a National Pollutant Discharge Elimination System permit pursuant to Section 402 of the Federal Water Pollution Control Act, or amendments thereto, and shall take effect ten days from the date of hearing, provided EPA has no objections.

IT IS HEREBY ORDERED, Homestake Mining Company and the property owner, in order to meet the provisions contained in Division 7 of the California Water Code and regulations adopted thereunder and the provisions of the Federal Water Pollution Control Act and regulations and guidelines adopted thereunder, shall comply with the following:

A. Prohibitions:

1. The discharge of domestic sewage, industrial wastes and runoff from ore stockpiles and process chemical storage/receiving areas, which is deleterious to fish, wildlife or other beneficial uses, is prohibited.

B. Effluent Limitations:

1. The discharge of an effluent in excess of the following limits is prohibited:

Constituents	Units	30-Day Average	Daily Maximum
Suspended Solids	mg/l	20	30
Settleable Solids	ml/l	1.0	5.0
Arsenic	mg/l	0.05	0.10
Cadmium	mg/l	0.01	0.02
Chromium	mg/l	0.05	0.10
Copper	mg/l	0.15	0.30
Mercury	mg/l	0.001	0.002
Lead	mg/l	0.05	0.10
Zinc	mg/l	0.75	1.5

Metals shall be analyzed and reported as totals.

2. The discharge shall not have a pH less than 6.5 nor greater than 9.0.

3. The Discharger shall use the best available technology to limit mineralization to no more than a reasonable increment.

4. Discharge to surface waters shall be limited to discharge from the sediment control ponds.

C. Receiving Water Limitations:

1. The Discharger shall not cause the dissolved oxygen concentration in Hunting or Knoxville Creek to fall below 5.0 mg/l.

2. The discharge shall not cause visible oil, grease, scum, foam, floating or suspended material in the receiving waters or watercourses.

3. The discharge shall not cause a measurable increase, over upstream levels of the receiving waters, of the following constituents: Arsenic, Lead.

4. The discharge shall not cause a statiscally significant, incremental increase of more than 10% (or, if greater than 10%, the minimum percentage increase that may be accurately measured) over upstream levels of the receiving waters, of the following constituents: Mercury, Chromium, Cadmium, Boron, Copper, Nickel.

5. The discharge shall not cause sedimentation or concentrations of any materials in the receiving waters which are deleterious to human, animal, aquatic, or plant life.

6. The discharge shall not cause esthetically undesirable discoloration of the receiving waters.

7. The discharge shall not cause fungus, slimes, or other objectionable growths in the receiving waters.

8. The discharge shall not cause bottom deposits in the receiving waters.

9. The discharge shall not increase the turbidity of the receiving waters by more than 10% over immediately upstream levels.

10. The discharge shall not alter the pH of the receiving water more than 0.5 units from immediately upstream levels.

11. The discharge shall not increase the temperature of the receiving water more than 5°F (3°C) from immediately upstream levels.

12. The discharge shall not cause a violation of any applicable water quality standard for receiving waters adopted by the Board or the State Water Resources Control Board as required by the Federal Water Pollution Control Act and regulations adopted thereunder. If more stringent applicable water quality standards are approved pursuant to Section 303 of the Federal Water Pollution Control Act, or amendments thereto, the Board will revise and modify this Order in accordance with such more stringent standards.

13 This permit shall be modified, or alternatively, revoked and reissued, to comply with any applicable effluent standard or limitation issued or approved under Sections 301(b)(2)(C), and (D), 304(b)(2), and 307(a)(2) of the Clean Water Act, if the effluent standard or limitation so issued or approved:

(a) Contains different conditions or is otherwise more stringent than any effluent limitation in the permit; or

(b) Controls any pollutant not limited in the permit.

The permit as modified or reissued under this paragraph shall also contain any other requirements of the Act then applicable.

D. Provisions:

1. Neither the discharge nor its treatment shall create a nuisance or pollution as defined in Section 13050 of the California Water Code.

2. The settling ponds shall be designed to contain the flow from the 10 year frequency storms in a 24 hour period.

   Annually, prior to the rainy season, the settling ponds shall be inspected and maintained to ensure the design capacity is provided.

3. The Discharger shall comply with all the items of the "Standard Provisions and Reporting Requirements (NPDES)", dated 1 January 1982, which are part of this Order.

4. The Discharger shall comply with the attached Monitoring and Reporting Program No. _____ as ordered by the Executive Officer.

5. This Order expires on 1 August 1988 and the Discharger must file a Report of Waste Discharge in accordance with Title 23, California Administrative Code, not later than 180 days in advance of such date as application for issuance of new waste discharge requirements.

6. In the event of any change in control or ownership of land or waste discharge facilities presently owned or controlled by the Discharger, the Discharger shall notify the succeeding owner or operator of the existence of this Order by letter, a copy of which shall be forwarded to this office.

7. The provisions of this Order are not intended to, and shall not limit or reduce any obligations or requirements which are additional to, or more stringent than, those created pursuant to this Order and which are imposed on the Discharger pursuant to (a) the terms of any agreement to which the Discharger is a party, including but not limited to, that certain agreement dated as of 30 June 1983, by and between the Discharger and the Solano Irrigation District, or (b) the requirements and controls imposed by any governmental agency or other authority having jurisdiction with respect to the Project. Nothing in this paragraph shall be construed to release or excuse the Discharger from full and timely compliance with the requirements of this Order or amendments or supplements hereto.

I, WILLIAM H. CROOKS, Executive Officer, do hereby certify the foregoing is a full, true, and correct copy of an Order adopted by the California Regional Water Quality Control Board, Central Valley Region, on _____.

CENTRAL VALLEY REGION

MONITORING AND REPORTING PROGRAM NO. _____

NPDES NO. CA0081477

FOR
McLAUGHLIN MINE
HOMESTAKE MINING COMPANY
AND
US BUREAU OF LAND MANAGEMENT
YOLO, LAKE AND NAPA COUNTIES

Sample stations shall be established such that the samples are representative of the volume and nature of the discharge.

EFFLUENT MONITORING

During each discharge period, the discharge from each settling pond (discharges 001, 002, 003, 004, 005) shall be sampled and analyzed according to the following schedule:

Constituent	Units	Type of Sample	Frequency
Flow	Gallons per day	Estimate	Daily
Temperature	°C	Grab	Daily
TDS	mg/l	Grab	Daily
EC	umhos/cm	Grab	Daily
pH (field)	pH units	Grab	Daily
pH	pH units	Grab	Daily
Suspended Solids	mg/l	Grab	Daily
Settleable Solids	ml/l	Grab	Daily
Total Alkalinity	mg/l	Grab	Daily
Calcium	mg/l	Grab	Daily
Chloride	mg/l	Grab	Daily
Nitrate	mg/l	Grab	Daily
Sulfate	mg/l	Grab	Daily
Ammonia	mg/l	Grab	Daily
Boron	mg/l	Grab	Daily
Arsenic	mg/l	Grab	Daily
Barium	mg/l	Grab	Daily
Beryllium	mg/l	Grab	Daily
Cadmium	mg/l	Grab	Daily
Chromium	mg/l	Grab	Daily
Copper	mg/l	Grab	Daily

Constituent	Units	Type of Sample	Frequency
Iron	mg/l	Grab	Daily
Lead	mg/l	Grab	Daily
Magnesium	mg/l	Grab	Daily
Manganese	mg/l	Grab	Daily
Mercury	mg/l	Grab	Daily
Nickel	mg/l	Grab	Daily
Sodium	mg/l	Grab	Daily
Selenium	mg/l	Grab	Daily
Vanadium	mg/l	Grab	Daily
Zinc	mg/l	Grab	Daily

Metals shall be analyzed and reported as totals.

RECEIVING WATER MONITORING

Receiving water samples shall be collected daily during periods when discharge is occurring. All samples shall be grab samples taken near mid-stream, where safety permits. Samples shall be taken from each sampling station and analyzed for the following constituents:

Station	Description
R-1	Hunting Creek, upstream of tailings disposal pond or at the northern end of the tailings stormwater diversion ditch
R-2 (HC-9)	Hunting Creek, 1/2 mile downstream of tailings dam
R-3 (HC-5)	Hunting Creek, 1/2 mile upstream of Waste Rock Disposal area
R-4 (HC-10)	Hunting Creek, 1/2 mile downstream of Waste Rock Disposal area
R-5 (KC-3)	Knoxville Creek, 1/4 mile west of Knoxville

Constituent	Units
Flow	Gallons per day
Temperature	°C
TDS	mg/l
EC	umhos/cm
pH (field)	pH units
pH	pH units
Suspended Solids	mg/l
Settleable Solids	ml/l

Constituent	Units
Total Alkalinity	mg/l
Calcium	mg/l
Chloride	mg/l
Nitrate	mg/l
Sulfate	mg/l
Ammonia	mg/l
Boron	mg/l
Arsenic	mg/l
Barium	mg/l
Beryllium	mg/l
Cadmium	mg/l
Chromium	mg/l
Copper	mg/l

Lead	mg/l
Magnesium	mg/l
Manganese	mg/l
Mercury	mg/l
Nickel	mg/l
Sodium	mg/l
Selenium	mg/l
Vanadium	mg/l
Zinc	mg/l
Turbidity	NTU

Metals shall be analyzed and reported as totals.

REPORTING

In reporting the monitoring data, the Discharger shall arrange the data in tabular form so that the date, the constituents, and the concentrations are readily discernible. The data shall be summarized in such a manner to illustrate clearly the compliance with waste discharge requirements.

Monthly monitoring reports shall be submitted to the Regional Board by the 15th day of the following month.

If the Discharger monitors any pollutant at the locations designated herein more frequently than is required by this Order, he shall include the results of such monitoring in the calculation and reporting of the values required in the Discharge Monitoring Reporting Form. Such increased frequency shall be indicated on the Discharge Monitoring Reporting Form.

The Discharger shall submit a report to the Board by 30 January of each year containing both tabular and graphical summaries of the monitoring data obtained during the previous year. In addition, the Discharger shall discuss the compliance record and the corrective actions taken or planned which may be needed to bring the discharges into full compliance with the waste discharge requirements.

The Discharger shall implement the above monitoring program on the effective date of this Order.

INTRODUCTION

Gold Fields of South Africa have examined aspects of water conservation since 1978 when a Water Committee was formed.

Kloof is one of the Gold Fields of South Africa Ltd. Mine - Mill complexes which has been selected to test ways of reducing water purchases from the Rand Water Board through developing technology for increased recycle of water. A systems approach has been employed which involves the mine, mill, tailings dam and sewage reclaim water.

During this investigation it was still too early for detailed data from Kloof to be released. No visit was made to the property. However, some general information was gathered about some of the new approaches being tested at Kloof, including:

1) Treatment of reclaimed sewage water for use in cooling of underground workings.

2) Underground hydropower generation using the hydrostatic head from surface water.

3) Removal of algae, bacteria and other pollutants from sewage treatment plant effluent by dissolved air flotation after $FeCl_3$ addition.

4) Removal of PO_4^{3-} and NH_3 by activated sludge treatment - the Badenpho Process.

5) NH_3 removal by adsorption on clinoptilolite clays.

Most of the above work was in the development and testing stages and no firm decisions were believed to have been taken as to what route to go in the commercial installations.

DESCRIPTION OF OPERATION

Kloof is rated as one of the finest gold mines in the world, and is located 40 kilometers west of Johannesburg on the West Witwatersrand Line. Gold ore occurs down to 13,000 ft. below the surface and ore grades of about 21 g Au/t are typical over a reef thickness of 1.5 meters in the VCR reef. During 1984 2.08 million tons of ore were mined to produce 31.9 tons of gold. Published operating costs are around R72 (US$50.0) per ton milled, which worked out to about US $104/ounce gold.

Being a deep mine high temperatures are experienced and underground cooling using refrigerated water represents a major use of water.

WATER SUPPLY

Kloof has historically relied on water supplied by the Rand Water Board at a cost of around R0.21/m^3 in 1984.

WATER CONSERVATION

Due to the serious drought in the Transvaal from 1982-4 it became essential to cut back on water consumption. Kloof reduced RWB consumption by 33% in 1984 compared with 1983. Much of these savings were achieved by improved housekeeping.

Further savings were envisaged through:

1) Recycling of sewage reclaim water for use in underground cooling.

2) Use of underground fissure water.

Already Kloof reclaims about as much water from their gold plant tailings as is likely to be possible. RANDOL has no information on how much otherwise reclaimable water is lost through seepage from the tailings dam and water impoundments.

TREATMENT OF RECLAIMED SEWAGE WATER FOR USE IN COOLING OF UNDERGROUND WORKINGS

South African gold mines are labor intensive operations. Large numbers of workers live on mine hotels and townsites near the mine and generate a large volume of sewage. The large mine population also uses a lot of potable water - ranging from 0.4 - 0.8 m^3/man/day. A significant savings in purchased water could be achieved if reclaimed sewage water could be used in the mine and mill to replace RWB water.

Because semi-skilled mineworkers are accustomed to drinking water underground "where they find it," all minewater is disinfected by chlorination.

There are three factors that have to be overcome in using reclaimed sewage water for underground cooling.

- Ammonia if present in high concentrations in the reclaimed water, causes corrosion of Cu-Ni coils in the refrigeration plant.
- Ammonia consumes chlorine at the rate of 10 Cl_2 per 1 NH_3 which makes it potentially costly to disinfect reclaimed sewage water.
- The presence of organic compounds in the sewage water raises a possibilty of generating toxic organohalogen compounds during chlorination.

CORROSION OF REFRIGERATION TUBES

The Cu-Ni refrigeration tube corrosion problem was not found at Kloof because the treated sewage effluent contains only about 0.5 mg NH_3-N/l. This is a good testimonial to the type of sewage treatment process in use at Kloof which is believed to be the BADENPHO Process. Their sewage plant is shown below.

DISINFECTION

In order to disinfect water before it goes underground 10 parts chlorine are consumed per 1 part NH_3 to achieve breakpoint chlorination which is normally considered necessary to be effective. Since typical treated sewage water pumped from the Kloof treatment plant contains less than 25 ppm NH_3, this would mean an additional consumption of at most 250 ppm Cl_2.

The National Institute of Water Research, Pretoria pointed out that even when only small amounts of chlorine are added as HTH (hypochlorite), in amounts way below that needed for breakpoint chlorination no coliform bacteria are detected in the water. This suggests that the chloramines formed by reaction between ammonia and chlorine may be adequate for disinfection without the need to go to breakpoint.

Dissolved air flotation for phosphate removal was also found to result in an effective removal of phenols which on chlorination could form toxic chlorinated phenols in the treated water.

UNDERGROUND HYDROPOWER GENERATION

To make use of the potential energy being supplied from the surface, two types of hydropower are being developed for use underground in South African mines:

a) hydroelectric generation

b) hydraulic power for drills, etc.

The water is delivered underground via high pressure pipes designed to withstand the high hydrostatic head. This hydrostatic pressure can be used to drive a pelton wheel coupled to a generator or to a pump. SULZER BROS Pty Ltd., a South African company has already supplied several units to South African mines including the unit to be installed at Kloof.

Another benefit of this energy recovery is that the chilled water remains cold, the pelton wheel harnessing the energy which would otherwise be absorbed by the water.

The second way to use this hydrostatic head is to drive hydraulic tools such as drills etc. This development work has recently been announced by the Chamber of Mines Research Laboratories which claims significant successes.

The Chamber of Mines Research Laboratories declined to provide more information on the technology which is soon expected to become a common practice for deeper mines. One of the needs of such a system is a way to efficiently remove particulate matter from the water used in this way to avoid unnecessary abrasion.

CONCLUSIONS

Numerous approaches are being investigated at Kloof Mine in conjunction with Gold Fields of South Africa Ltd. and the National Institute for Water Research, to water conservation through further recycling and reuse of sewage water, but it is still too soon to report any definite results.

INTRODUCTION

Rand Mines Milling and Mining Ltd. (RM3) reclaims old sand and slimes tailings dumps on the outskirts of Johannesburg. The dumps concerned have been prominent landmarks on the western edge of the City of Johannesburg and the operation is an excellent example of how a very large (over 15,000 tpd) gold and pyrite recovery plant, including cyanidation, can operate safely and compatibly in a built-up area.

RM3 uses as much recycled water and as little Rand Water Board water as possible. Considerable amounts of surface water from a stream on the property are used.

Poor water quality has been suspected for metallurgical results in the commercial scale plant that did not match the better results indicated in pilot plant tests, particularly in the CIP performance.

RM3 tries to segregate water used in the cyanidation and CIP circuit from that used in the flotation and classification steps which requires some careful water management considerations. Several water quality factors were identified by RM3 as having possible negative impact on gold recovery, and corrective measures could overcome some of these. However, in examining the flowsheet superficially from a water management viewpoint RANDOL is of the opinion that the potential exists to seek additional metallurgical improvement and perhaps some cost savings through further investigation of water quality factors relating firstly, to the extensive recycling of water in the front end of the plant including flotation and, secondly, due to the source of some of the water used.

These speculative expectations are based on preliminary and superficial information but are focused on here as an interesting illustration of some of the considerations that must be taken into account when water is recycled and as an example of the complexity and usefulness of adopting a systems approach to water management and also as an example of how viewing a metallurgical operation from a water and salt balance standpoint, a whole new perspective may be found of factors that can influence metallurgical performance.

Rand Mines and RM3 staff have not discussed metallurgical performance with RANDOL and gold recovery performance is not known for sure, but it is believed to be around 70% compared with 75% indicated in the pilot operation. Rand Mines Ltd. and RM3's forgiveness is asked for the following speculative discussion basen on only partial facts which must therefore be largely hypothetical, but which is offered in a constructive, helpful spirit.

DETAILS OF OPERATION

Capital Cost	R60 million (US$33 million)
Reserves of Feed	60 million tons
Recovery	0.5 g Au/t
Operating Costs	R11.60/g = R5.80/t ($5.60/g = $2.90/t)
Plant Throughput	4.4 million tpa sand plus slime
1983 Recovery of gold	About 70% at design capacity
Design Recovery	75%

ENVIRONMENTAL IMPACT OF RM3

Although the facts and conclusions are not yet available from a study of the subject, it is expected that Witwatersrand tailings do oxidize with time and are a source of acid mine drainage. This is believed to contribute to the diffuse source total dissolved salts that impacts the macro water supply system for the area.

Removal of pyrite from tailings by operations such as RM3 represents a reduction in the amount of pyrite left to oxidize and therefore can be expected to be beneficial in the national campaign to improve water quality.

In order to improve the grade of the pyrite concentrate RM3 has deliberately reduced flotation recovery efficiency which means that the amount of residual pyrite left in the tailings will be more than in the original design. It is not known to what extent the residual pyrite levels will possibly generate acid in the future.

It is interesting that when it was announced that the mine dumps around Johannesburg were to be reprocessed, a society was formed for the preservation of the dumps which had become a familiar landmark and wildlife refuge in the city limits.

DESCRIPTION OF PROCESS

RM3 processes sand and slimes tailings dump material to recover gold and a pyrite-gold flotation concentrate.

Sand tailings are classified into a coarse sand and a slime fraction. The coarse fraction is floated at pH 3.5-4.0 to recover a pyrite concentrate. The flotation tailings are ground to 50% minus 200 mesh and together with the slimes fraction are cyanided followed by gold recovery using CIP. The flotation concentrate consisting of a pyrite concentrate with higher gold values is ground to 95% minus 200 mesh, cyanide leached and gold recovered in a second CIP plant.

The main water management target is to use more tailings return water in the plant. At present water is managed in two separate circuits namely the low pH flotation circuit at pH 3.5-4.0 and a high pH gold leach, CIP, tailings and dam return water system.

The principle flowsheet is illustrated overleaf showing the main operating units. The main internal water recycling pathways are shown by dashed lines.

Attrition of particles in the flotation step scrubs the particles ahead of milling and leaching and it is believed to result in enhanced leach recovery.

The concentrate leach was designed for a feed with 28% sulfide and 6 g Au/t. The plant was operating in 1984 at a feed of 40% sulfur and 15 g Au/t in the leach. It is suspected that possibly soluble sulfide in the pulp solution may deplete dissolved oxygen. RANDOL believes that this can be at least partially overcome by a preaeration step if inserted into the water recycling circuits around the flotation and/or repulping steps.

Originally the plant was designed to treat 325,000 tpm sand to yield 8600 tpm of concentrate at 28% S, i.e. 2410 tpm sulfur. In the 1984 operating arrangement 375,000 tpm sand was being treated to yield about the same amount of sulfide in only 6000 tons/month of concentrate with a grade of 40% S and 15 g Au/t.

RM3 FLOWSHEET

WATER RECYCLING

The RM3 process arrangement has several water recycling loops, e.g.,

1) Sand Repulping
   Classifier Cyclone overflow
   Thickeners $15m^2$ o/f
   $40m^2$ Thickener o/f
   "Industrial" water tanks
   Back to repulpers at 800 m^3/h

2) Dilution of Classifier Cyclone u/f — $475m^3/h$
   Flotation
   Flotation tailings dewatering Cyclone o/f recycle water — $617m^3/h$
   Flotation Tailings Dewatering Screen u/f — $1120m^3/h$

3) Flotation tailings dewatered
   Grind
   Add slimes
   Leach
   CIP
   Tailings dam
   RDS Recycle to CN tank — $230m^3/h$
   CN tank to slimes monitoring
   Slimes to mill outlet or direct to 1st stage leach

The water recycling and reticulation system is clearly complicated. Water used for repulping and classification of the feed is recycled in the first loop.

In the second loop acidic water used to dilute the sand fraction ahead of flotation is recovered to as great an extent as possible and recycled back to dilute feed to the flotation circuit.

High pH water used in the cyanidation - CIP circuit is recycled via the tailings dam reclaim dam solution via the "Cyanide" water tank.

Low pH water is kept in the flotation circuit which results in a better flotation recovery. Cyanide bearing solutions are kept from the flotation circuit where cyanide would depress pyrite recovery.

Use of tailings dam RDS in the slimes and ground sand cyanidation circuit has resulted in a drop in lime and cyanide consumption without noticeable adverse effects on gold recovery.

RM3 WATER RETICULATION

In order to increase the use of RDS, RM3 would like to treat it in a carbon column to recover residual gold and destroy cyanide before more of this water is used in the front end of the process. Treated RDS is also being considered for potential use as pump gland service water. These possibilities appear to be realistic.

Advantages of Using More RDS

1) Reduced requirement of Rand Water Board water
2) Allow the tailings dam water level to be dropped thereby reducing evaporation losses.
3) Save on lime and cyanide consumption.

Currently only about 33-34% of the water pumped to the tailings dam is recovered - amounting to some $230m^3/h$.

Water Quality Influences and Effects

1) RM3 dumps have a naturally low pH due to pyrite oxidation which result in pH levels down to 2.5 in repulped tailings. The low pH is claimed to be beneficial for gold/pyrite flotation recovery, e.g.,

   - Reduced tendency for fines agglomeration
   - Improved pyrite concentrate grade (A rougher concentrate with 40%S is achieved)
   - Reduced reagent consumption for flotation
   - Better leaching characteristics of flotation tailings - use of Xanthates is avoided
   - By operating the flotation at a low pH 3.5 - 4.0 it is possible to use flotation reagents such as merkaptothiazol and thiophosphate which are believed to be less stable at an alkaline pH, so once the flotation tailings are neutralized the reagents degrade rapidly to shorter chain molecules which have less adverse effect on leaching and CIP performance.

2) Local creek water is used in the process. Some metallurgical problems were ascribed to the use of this water which is generated by runoff from a local catchment including several tailings dams. This water proved to be contaminated by about 50 ppm organics which caused metallurgical problems. It was believed that an industry generating fats, located upstream was possibly responsible for the contamination.

3) Initially the startup of the flotation circuit had to be postponed because it was found that the original flotation reagents caused an interference with the CIP recovery of gold.

   The original frother used was a polyglycol supplied by Hoechst, called Flotinol C7 Polyglycol. Only 0.5 ppm of this reagent was added and the evidence of CIP interference caused by this reagent was not conclusive. However, the plant switched to a NCP (National Chemical Products) frother known as TEB.

4) Oils and greases in the feed may also have interfered with the CIP performance. Originally there was not an effective oil trap on the compressed air system and the compressors operated at a high temperature. It is known that carbon adsorption of gold can be impaired in this way.

5) In the concentrate regrind circuit lime and concentrate are added to the pumpbox ahead of the cyclone in the circuit. If milled in acid steel consumption would be excessive so the pulp is neutralized. In general, where possible, it is believed that better results would be achieved if the concentrate could be milled in an acid pH which would result in a lower viscosity. There might be some motivation to test stainless grinding media.

6) In examining the tailings sand and slimes repulping steps it is observed that there has been enough oxidation of pyrite in the feed to cause pH to drop as low as pH 2.5 at times. This undoubtedly introduces ferrous iron, sulfate and some soluble sulfides into the pulp solution. As this acid water is recycled it would be logical that Fe^{3+}, Fe^{2+}, $SO_4^{=}$, $S^{=}$, etc. would build up in concentration. Some will be dropped out by lime treatment in the 40m thickener, however not necessarily all. Also as water is recycled around the flotation step, undoubtedly more salts will build up in concentration in the solution. Some solution is always transferred with the pulp in thickener underflows.

It is suspected that as a result of this continuous recycling of water in contact with partially oxidized feed containing sulfides and iron, the oxygen level of the pulp is likely to be depleted. (The adverse effects of pyrrhotite in ores on leaching and CIP in other locations is well known.)

It is possible that aeration in the flotation step may partially oxidize soluble sulfides but residence time will be too short at the low pH to oxidize ferrous iron in the pulp.

RANDOL suggests that the oxygen, ferrous, sulfide, and thiocyanate levels in the recirculating water and in the pulp advancing from flotation to leaching be carefully checked as a possible contributor to metallurgical efficiency reduction in the subsequent steps.

In the event that there are residual sulfide and ferrous ions in the feed to the leaching and CIP plant, then the expected symptoms would be difficulty in effective elution of gold from activated carbon as was initially experienced at Homestake's CIP plant prior to insertion of an effective preaeration step. However, at RM3 no difficulty in eluting gold from carbon is experienced and levels of 10-50g Au/t are routinely achieved.

7) Water sources used and the recycled solutions at low pH should also be checked for $CO_3^{=}$ content. If carbonate has built up in these solutions then consideration should

be given to the economic advantages of removing CO_2 by vigorous aeration ahead of lime addition steps. This could reduce lime consumption and also the volume of sludge generated and possibly also reduce scaling of carbon in the CIP plants.

ELUTION AND REGENERATION OF CARBON

It is noted that as a result of higher gold levels in the concentrate feed and because of lower carbon loadings, carbon was being advanced through the elution and regeneration circuit at three times the original design rate of 4 tpd. All loaded carbon is acid treated ahead of elution.

The original design called for regeneration of carbon every cycle at 4 tpd. Since now 12 tpd are being eluted, the existing Bohler rotary regeneration kiln with a capacity of 210 kg C/hour is only able to handle 5 tpd. The Rintoul electric carbon regeneration unit can treat 4 tpd to give a total capacity of 9 tpd. This means that each day at least 3 tons of carbon must bypass the regeneration kilns.

Operating the carbon regeneration kiln continuously for 24 hours per day is believed to improve its operation.

The carbon dewatering step ahead of the regeneration kiln has been modified to allow less water to reach the kiln with the carbon which RM3 believes will improve CIP performance. RM3 was also experimenting with carbon drying techniques ahead of regeneration to make the existing regenerating equipment more effective. Even though some carbon is not regenerated each cycle it is not known whether the same applies to the acid washing step as well.

CONCLUSIONS

There remain questions and points to test to determine whether the float-leach-CIP sequence and recirculation of water to treat partially oxidized tailings containing pyrite has an impact on water quality which has a negative impact on cyanide leaching and/or recovery of gold by CIP.

Additional water treatment measures should be tested in the circuit. Some of these are simple and inexpensive. RM3 is presently persuing an investigation to identify the solution phase contaminants with a firm of water treatment suppliers.

INTRODUCTION

This 3000 tpd heap leaching operation which shut down in the fall of 1984 is located in steep mountainous country alongside creeks that flow into important salmon spawning and fishing grounds. The value of the tourist industry attracted by the sport fishing makes it essential that the mining operation not contaminate the creek. The mine and metallurgical operations are on national forest land just 3 miles from the River of No Return Wilderness area. The project started up in July 1983. Topography consists of steep-sided canyons and swift- flowing streams. More information is available in STOTT (1984).

Main areas of concern are:

- Introduction of particulate material into the stream which could damage the riverbed.
- Introduction of heavy metals and/or cyanide which are toxic to fish.

DATE OF VISIT 16 October 1983

LOCATION 95 miles northeast of Boise, Idaho

OPERATION

400,000-500,000 tons per year ore is crushed to 1½" x O. 1.5 lbs of lime are added per ton of ore during the crushing step to neutralize the ore which is leached at pH 10-11.

The ore is clay rich but agglomeration tests did not indicate an improvement in recovery so the ore is not agglomerated.

The 10' high 30,000t heaps are subjected to a 50 day leach cycle:

10 days	build heaps
20 days	leach
10 days	wash and cyanide destruction
10 days	remove heaps

Solution is applied to the 250' x 350' heaps at a rate of 0.3 gph/ft^2 (0.005 gpm/ft) i.e., 2500 lb/minute per heap. The heaps are stacked on a specially prepared asphalt pad covered by 18" ore layer to protect the pad. The heaps are located only 300 ft from the Salmon River and one mine pit is situated on the banks of the West End Creek. Special environmental protection measures are adopted in the operation to protect water quality in the creeks and river:

Mining

The West End Creek has been diverted. It was impossible to work the lower levels of the mine without sidecasting into the creek. There was also no room for ponds to hold runoff water from the mine. Consideration must also be given to limiting the transfer of clay slimes from the mine area and haul roads to the rivers in runoff water - a problem not yet satisfactorily solved at the time of the Randol visit. Fish and Game trick: Use straw bales to dam and settle solids in runoff areas.

Metallurgical

A multiple layer pad has been prepared for the heaps together with a monitoring system to be doubly sure no cyanide solutions reach the groundwater.

Prepared surface covered with 1-2" layer of 100# tailings and compacted
30 mil PVC
Geotextile fabric layer
12" washed gravel to give compentency to pad
3" asphalt
Emulsion Seal SS11 or S11
18" ore layer over the asphalt protects it while heaps are placed or removed. A more detailed description is provided by STOTTS (1984) below.

Cyanide Detoxification

1) $Ca(OCl)_2$ generated at the site from lime and chlorine gas and the $CA(OCl)_2$ solution is sprayed over the heaps to destroy residual cyanide in the heaps.

   2 d drain after leaching
   6 d wash with $Ca(OCl)_2$ solution
   2 d drain after leaching

2) CN destruction uses the same sprinkler system that was used to apply the CN^- solution. This time, however, CN^- nutralization pond water is used at pH 12-13.

3) At all times 3.5 tons of $Ca(OCl)_2$ are kept on hand in case the $Ca(OCl)_2$ manufacturing system should fail.

4) Hydrogen peroxide was also tested for cyanide destruction in a test column by Heinen Lindstrom Associates in Reno, Nevada and was found to be less efficient.

5) The CN^- levels are monitored regularly in the "off" solution during chlorination.

   CN^- is monitored at ppb levels in the 10 monitor wells using a Hachmeter Model DR100 calorimeter Model 41100

   Hach Co.
   Box 389
   Loveland, CO

   The heaps are chlorinated before the leached heaps are placed on the tailings dump. It is also required that any heap that may be being leached when it freezes should be neutralized. If left over winter CN^- could leak with spring runoff. In case a freeze occurs, the system is fitted with a 50 HP Boiler and heat exchanger to warm the solution which is applied at 240 gpm.

6) Pebble lime is used because slaked lime tends to blow around and is unsightly.

7) Chlorine is added via an eductor in the line which doses and mixes the chlorine solution. Pennwalt supplies Cl_2 @ \$360/t in cylinders. There are 10 cylinders hooked up to the Cl_2 system.

8) By converting from NaOH to $Ca(OH)_2$ for pH control on the heaps it was found that NaCN consumption dropped from 1½ lb/t ore to 0.2 lb NaCN/t ore. Suspected on the basis of lab tests that NaOH solubilizes Fe or other base metals which consume CN^-.

9) First heap neutralized at regular pH 10 took 22 days to bring CN^- in "off" solution to below 0.2 ppm CN^- by bringing pH up to 12-13 with $Ca(OH)_2$ the reaction is much faster (6 days).

10) When using pebble lime for $Ca(OCl)_2$ grit gets into the solution which clogs the sprinklers. This is overcome in practice by temporarily turning the lime supply off which allows the pH to drop due to reaction of Cl_2 with water to yield HCl.

11) A 1 mm gallon pond is used to contain neutralization solution.

Cost of Cyanide Detoxification

1¼ lb lime is consumed per lb Cl_2 added in the chlorination step. 4,000 lbs Cl_2 per day is added to solution which is applied at 240 gpm.

This works out to 12 tons Cl_2 consumption per heap of 30,000 t ore tailings or $4300/heap ($360/t Cl_2), which works out to $1.14/ton ore.

Monitoring and Environmental Aspects

Environmental consultants who supervise the groundwater monitoring - 10 monitor wells are:

James Montgomery Engineering
Boise, ID office
Headquarters in Los Angeles

Aug 1 - Sept 15 - No chemical reagents are hauled along the roadway to the plant in case of an accident which could spill reagent into the stream.

Before this operation started, old tailings of a former 1938 tungsten mine were getting into the river. These tailings were high in Fe, very fine and silted up the bed of the Salmon River. These tailings are now covered with minus 1½" HL material which now supports grass growth and prevents silt from getting into the River.

DATE OF VISIT	11 January 1984

INTRODUCTION

Vaal Reefs is one of the very largest gold producers in the world, with three gold and three uranium milling operations in the complex producing a total of 9.7 million tons/year ore at an average grade of around 8 g Au/t. Vaal Reefs is also responsible for operating the new Afrikander Lease plant which was originally designed as a pressure leaching uranium plant, but only the milling and gold recovery circuit is being used - conventional cyanidation followed by CIP.

Apart from being awe-inspiring on account of its size, Vaal Reefs is fascinating because of the variety of different metallurgical circuits employed. The complex is divided into East, West and South Divisions. The South has two gold plants and a uranium plant while the other two divisions each have a gold plant, a uranium plant, a flotation plant, an acid plant and a calcine plant. The complex covers many tens of square kilometers with hundreds of miles of water, solution and tailings lines linking the operations.

From a water management point of view Vaal Reefs represents an enormous challenge. Since water has historically been inexpensive (and still is) and since effluent disposal,

conservation of water, groundwater quality protection, etc. have been non-critical issues in South Africa until the recent 1982-4 drought, most South African mining and milling operations have had to adapt to a sudden need for change.

When there is just one mine and mill in a complex, water management can represent a challenge especially if it has to be "retrofitted." For an operation with numerous shafts and underground workings requiring cooling, five gold plants and three uranium plants and a huge labor force requiring large amounts of potable water and generating equally large amounts of sewage, establishing an integrated comprehensive water plan is very expensive and time consuming. Because of the complexity of the system, it has also taken longer to develop the plan.

As of January 1984 a quantitative water balance had yet to be drawn up. With such a complicated array of unit operations installed over many years, the establishment of a detailed water balance is no small undertaking. First, it is necessary to find the layout of all flows and then to measure them. The 1984 budget for instrumentation alone to measure flow rates and draw samples was R500,000 ($300,000).

With side-by-side uranium plants using a highly acidic process and gold plants using alkaline cyanidation, extreme caution is necessary to avoid acidification of cyanide streams which would generate toxic HCN.

In response to the national emergency brought on by the drought of 1982-4, Vaal Reefs was able to save 35% on water consumption in 1983 over 1982. Presumably much of this savings came about through improved housekeeping and by instilling in operators an awareness of the need to save water, e.g., closing taps, metering water use in hostels, etc.

Once a quantitative water balance has been established for each mine and each metallurgical operation, Vaal Reefs will be able to design a water conservation and effluent disposal plan. The company is acutely aware of the need and is responding diligently. Metallurgical staff are in charge of the water committee. At the time of the RANDOL visit it was possible to make only a few random observations. Once Vaal Reefs has completed their evaluation and implemented a plan which will probably take 12-24 months, it is likely that a most interesting water management story will emerge.

Vaal Reefs' annual new water consumption (plants only) amounts to 9.9 million m^3 to treat 9.2 million tons ore, i.e., 1.08 m^3 water/ton which is not excessive considering that this is for gold and uranium extraction. (These figures are for 1984 and have been projected to year end; they do not include Africander Lease.)

Vaal Reefs' annual water bill amounts to R1,000,000 (US $500,000) or R0.109/t ore (US $0.05/st) for water consumption costs which is relatively little. Cutting back on water consumption would make it possible to save on water costs, but these savings must be weighed against costs of scale inhibition and corrosion that may then arise as well as

possible impact on metallurgical recovery and reagent consumption which are likely to overshadow the actual water cost savings.

The current method of treating effluents at Vaal Reefs is rather unsophisticated but appears to be very effective - only expensive in terms of lime requirements. Comments made in this report as to ways that may make it possible to further improve water treatment and consumtion costs are purely hypothetical ideas.

MOTIVATION FOR WATER MANAGEMENT

Vaal Reefs has already achieved a significant water cost savings through implementing a water housekeeping and awareness program. Beyond cutting back on water wastage through operator carelessness, further water management improvements are unlikely to be motivated by savings in the cost of water at current price levels. The motivations are:

1) Anticipated stricter effluent discharge regulations including diffuse source discharge which may affect groundwater quality through seepage.

2) Uncertain future availability of regional water board supply and Vaal River water.

3) Likelihood of price hikes of regional water supplied to Vaal Reefs.

4) Possibility to recover additional incremental gold values from recycle solutions and effluent streams.

5) Reduction in cost of effluent treatment where lime is a major cost item.

CLIMATE

Temperate climate with 20" (500 mm) rainfall per year and an estimated evaporation of about 30" per year. Summer rainfall and dry cool winters.

PROCESSES

Gold is recovered primarily by conventional leaching followed by Merrill-Crowe. Uranium is recovered by sulfuric acid leaching followed by CCD, drum filtration and belt filtration in each of the three plants, followed by ion exchange and SX. At Afrikander Leases a pressure oxidation plant has been installed (but not commissioned) which leaches uranium followed by a CIP plant for gold. Heap leaching piles are under construction to recover residual gold from wasterock fines.

WATER CONSUMPTION (Latest figures include new gold plnat at No. 9 shaft being commissioned)

340,000 m^3/mo new water from the Water Board
535,000 m^3/mo river water from the Vaal
15,000 m^3/mo wellwater for Afrikander Leases
890,000 m^3/mo

Over 30 operating days/mo this works out to 30,000 m^3/d used to treat 29,000 tpd ore, or 1.03 m^3 new water per ton ore. (These figures include Afrikander Lease.)

COST OF WATER

Regional Water Board	R0.17/m^3	US \$0.09 /m^3
Vaal River water	R0.05/m^3	US \$0.024/m^3
Regional Water Board	R700,000/yr	US \$350,000
Vaal River water	R320,000/yr	US \$160,000
Total Annual Cost (1983)	R1,020,000	\$510,000

Considering the magnitude of the operation and the large amount of water used, this is a relatively low water bill, although further water savings would undoubtedly achieve a worthwhile additional cost savings. Note that these figures are for plants only. An additional 1,150,000 m^3/month is used for shafts, hostels and townships in the area and much of this water is recycled back to the plants via fridge plants and sewage plants.

WATER RECYCLING

Metallurgical managers indicated that at present all water that can possibly be reclaimed is recycled. Large amounts of water are currently recycled on a macro scale, and no effluents are deliberately discharged although, considering the design of most of the recycle water impoundments as evaporation dams, there are undoubtedly considerable losses of water through evaporation.

A general layout of the main ore processing units and how these are interconnected with respect to water flow is shown diagrammatically below. The diagram shows water reclamation for recycling as process water from the residue dams at Vaal Reefs North dam, Vaal Reefs South and Vaal Reefs West slimes and residue dams.

Water is reclaimed from areas marked as evaporation dams. Although aging of recycle solution is likely to result in some quality improvement the aims of evaporation and water recovery for reuse would appear to be contradictory. Sample 13 drawn from within evaporation area C appears to be saturated with gypsum which would be expected.

VAAL REEFS COMPLEX METALLURGICAL EFFLUENT DISPOSAL

Effluents from various unit operations are neutralized together with tailings pulps which results in the precipitation of gypsum onto tailings solids allowing solution to decant with no more than saturation levels of gypsum.

As much as possible of the reclaimable water from the tailings dams is recycled to the plant. The operators find that suspended solids is the only cause for concern about its quality.

Since the quality of reclaimed water seems to be excellent, the aims of the water management program are to recover more of it and to reduce the cost (lime consumption) of treating the effluents.

SEWAGE WATER RECYCLE

South African gold mining is labor intensive and large numbers of workers are accommodated, with correspondingly large sewage plants. Treated effluent from Vaal Reefs sewage plants is used as water in the gold plants. Sewage water use was tested on the West Plant for use in the gold and uranium processes and no ill effects were noted. In all there are five sewage plants on the Vaal Reefs complex, all of which employ biofilters.

REFRIGERATION PLANT BLEED WATER USE

A new gold recovery plant is to be commissioned in 1984 at 9 Shaft - at a cost of about R400 million including the 6000 ft shaft and plant. The 120,000 tpm gold plant capital cost was around R60 mm.

Chilled water is recirculated from the surface to the underground workings to cool the stopes. After being pumped back to the surface the water is cooled in a cooling tower and then refrigerated before going back underground. Each pass made by the water through the underground workings adds 1000 ppm TDS - including a considerable amount of nitrates. Water quality in the refrigeration loop is controlled by bleeding water which in the case of the new 9-shaft mine will be used in the gold plant.

WATER BALANCE STUDY

R500,000 had been allocated in the 1984 budget for sampling and flow measurement equipment to be installed to determine a detailed water balance at Vaal Reefs. Some innovative new sampling devices using solar power and batteries are being used.

Milltronics ultrasonic detectors are to be used for flow measurement. Portable solar power units are to be provided by Siemens. In house resources have been commissioned to provide computer services. ISCO samplers were installed; these are weatherproof and can

be operated from batteries or mains. A battery is good for 28 samples between recharging. The sampler with sample bottle casette costs R3000 and is manufactured by:

Instrument Specialties Co.
P. O. Box 82531
Lincoln, Nebraska 68501

Telephone: (402) 474-2233
(800) 228-4373

The sampler can be coupled to a flowmeter to take proportional samples if desired.

A firm of civil engineers had been hired as consultants to develop the detailed water flow diagram and water balance:

Jones and Wagener Pty Ltd.
Civil Engineers
P. O. Box 1438
Rivonia 2128

Contact: Fritz Wagener
John Wates

The objectives of the water balance study include a determination of whether or not to use sewage water in the metallurgical plants and to be able to predict and manage the seasonal availability of water that can be used for recycling.

WATER QUALITY

Contaminant levels in water sampled at various points in the water flow diagram and indicated by number, are shown in the table that follows the diagram.

From this table it is clear that:

1. There is virtually no increase in TDS in the Vaal River from the point of entry to the point of leaving the Vaal Reefs property: points 9 and 10. All other points measured close to the river are small seepage flows into the river: points 1 to 7.

2. Since manganese dioxide is used as an oxidant in all the uranium recovery operations, it is of interest that manganese in all the river water samples is less than 1 ppm. This is due to the effective removal of manganese by a lime treatment to pH 9.5 before tailings and effluents are discharged to the tailings dams. At the East and West divisions all the raffinate is neutralized together with the final residue and discarded on the slimes dams.

3. In April 1980 samples of effluent entering the river were measured at 5.5 ppm Mn and 65 ppm Mn. A uranium plant effluent was measured at 1300 ppm Mn which is not atypical of uranium plants that use manganese as an oxidant. Clearly the effluent treatment steps now employed have brought manganese levels in effluents under control.

4. Treated effluent composition is:

CN	less than	1	ppm
Cu	less than	1	ppm
Pb	less than	1	ppm
Zn	less than	1	ppm
Mg		150	ppm
Mn	less than	1	ppm
NO_3		30	ppm
$SO_4^{=}$		1000	ppm
Ca		550	ppm
Suspended Solids		20	ppm

This is a remarkably good water quality considering that it it reclaimed from a mixture of highly acidic uranium tailings, very high TDS raffinate and alkaline cyanidation gold barren solutions.

U Plant Effluents - Raffinate

Pregnant solution from the uranium plants is generated at the rate of 9000 m^3/d from the two Vaal Reefs East Plants and 9000 m^3/d from the three Vaal Reefs West plants for a total of 18,000 m^3/d from which uranium is extracted by SX. The resulting raffinate contains 25-30,000 ppm TDS at a very low pH.

Since the raffinate is a major consumer of lime in the effluent treatment system, consideration is being given to possibly treat and recycle this stream separately. Typical composition of U-plant raffinates on the Witwatersrand is:

Typical U-Plant Raffinate Composition

pH	1.5				
Na	300	ppm	CNS	Ø	ppm
K	70	ppm	Fe^{2+}	730	ppm
Ca	600	ppm	Fe^{3+}	500	ppm
Mg	130	ppm	NO_3^-	160	ppm
Cl	250	ppm	NH_3	0.1	ppm
HCO_3^-	Ø	ppm	F^-	0.1	ppm
$CO_3^{=}$	Ø	ppm	Mn	1670	ppm
$SO_4^{=}$	17,500	ppm	Heavy Metals	110	ppm
SiO_2	380	ppm	TDS	24,480	ppm
CN^-	33	ppm	Suspended Solids	750	ppm

EFFLUENT RECLAMATION PROCESSES

Effluents from various Vaal Reefs plants contain elevated levels of cyanide, copper, lead, zinc, mercury, manganese, arsenic, bismuth, ammonia, $SO_4^{=}$, calcium, suspended solids and others.

The effluents are currently treated by raising the pH to 9.5 by mixing pulp and effluents to yield an over-neutralized pulp with lots of iron added in the form of an acidic raffinate, all mixed in residue pachucas ahead of pumping the slurry mixture to tailings dams.

Effluent pulp treatment consumes 10-12 Kg lime per ton tailings slime treated.

At R80/ton CaO, the lime requirement would be 97,000 tpa lime costing R7,760,000 or $4.5 million per year.

The composition of tailings dam return water is:

CN	less than	1	ppm
Cu	less than	1	ppm
Pb	less than	1	ppm
Zn	less than	1	ppm
Mg		150	ppm
Mn	less than	1	ppm
NO_3		30	ppm
$SO_4^{=}$		2500	ppm
Ca		550	ppm
Suspended solids		20	ppm

EFFLUENT DISPOSAL

Water is lost from the system through evaporation from tailings dams and evaporation ponds. A significant amount of water is also lost by entrainment in tailings slimes.

Seepage from tailings dams, reclaim water ponds and evaporation ponds undoubtedly loses some potentially recoverable water. The magnitude of this solution loss has not been quantified.

According to the 1980 diagram of water flow effluents from Vaal Reefs East Gold and Uranium plants and from Vaal Reefs West slimes dam can be pumped to evaporation area A or to the water dam for irrigation of the wasterock dump adjacent to No. 3 shaft. It appears that irrigation of effluents to a wasterock pile would be an effective way to evaporate solutions, but also a potential source of seepage contamination of groundwater, or a source of runoff water contamination.

Disposal of all effluent streams including utility water processing concentrates, barren bleeds from the gold plant acid uranium tailings and raffinates via a central neutralization tank, etc. provides a simple but relatively expensive means of recycling water and precipitating undesirable contaminants. 10 to 12 Kg lime per ton solids is required for this purpose costing R0.80-R1.00 per ton which represents a fair percentage of the total metallurgical operating costs.

GOLD RECOVERY FROM RECYCLED WATER

Vaal Reefs employs carbon columns to recover gold from low grade streams of water at several points in the plant.

The gold plant filter tailings contain 0.4-0.5g Au/t undissolved and these then advance to the acid uranium leach operations. Final tailings contain only 0.25 gAu/t. The reason for this is that 40-50% of the gold is recovered in the flotation circuits in the complex. The gold is ultimately recovered in the calcine plants; i.e., after roasting of the pyrite. Tailings dam reclaim water at pH8-9 contains 0.01-0.03g Au/t as soluble gold.

1. Gold Recovery from Filter Wash Solution ahead of Washing

After filtration in the gold plants at the East and West divisions the filter cake is repulped with barren solution (ex the precipitation Stellars) and pumped to the Uranium Plants. This stream is refiltered to remove cyanide and improve the pulp density to the uranium leach. This filtrate is called "primary filtrate" and contains much of the gold plant soluble losses.

Vaal Reefs has for some time employed a set of fixed bed carbon columns to recover gold from primary filtrate. This column system and their performance was reported in Phase II of the Randol study "Innovations in Gold and Silver Recovery" Appendix II, page 398-402 and this information can be made available to Sponsors of this study on request.

2. Pinned Bed Columns

Anglo American Research Laboratories has developed a new concept of carbon adsorption columns known as the "Pinned Bed." This highly innovative gold recovery system has been proven in tests to be able to tolerate relatively high suspended solids levels - to the extent of treating dilute pulps, and to be particularly efficient at recovering gold from dilute solutions.

A pilot unit has been tested at the Vaal Reefs South Plant.

Results and description of this innovative design are confidential pending formalization of the patent applications but can be requested (once cleared for release) from:

Anglo American Research Laboratories Ltd.
P. O. Box 106
Crown Mines 2025
South Africa

Telephone: (011) 835-3251
Contact: Dr. Brian Loveday, Manager
Dr. Ray J. Davidson, Metallurgist

3. Au Recovery from Regen. Aqueous Solutions

Two sets of four small 14" Ø columns 6 ft. high in series are installed to recover gold from regen. aqueous solution used in the uranium SX plant at the East and West Divisions.

WATER TREATMENT PROCESSES

Apart from the effluent reclamation process, there are numerous other smaller needs for water treatment on Vaal Reefs plants. The sulfuric acid leaching of uranium requires steam heat and several boilers are employed.

Conventional boilers require very low levels of TDS to generate 600 psi steam. The Vaal Reefs boilers are simpler low pressure units and can tolerate 20 ppm TDS.

Vaal Reefs has installed a new type of R.O. module to treat reclaimed sewage water for use as boiler feed. This pilot unit is purely experimental and produces 1 m^3/hour.

The new tubular R.O. modules have taken an old R. O. concept and revitalized it by improving its design, cost and maintenance needs. More information on these R. O. modules and other innovative applications is provided in Chapter 15 on Reverse Osmosis.

The new R. O. modules installed at Vaal Reefs were supplied by:

Bakke Industries Ltd.
P. O. Box 344
Paarl
South Africa

Telephone: (02211) 23032
Contacts: D. B. Smit
Johan Barnard

Danie Bosman, Head of Environmental Services, Anglo American Research Laboratories has been involved in the applications development end of the Vaal Reefs R. O. installations (address given above.)

R. O. treatment of brackish water was estimated to cost R0.50/m^3 excluding capital cost items. The residues were being disposed of to the tailings dams.

ENVIRONMENTAL ASPECTS

Data provided by Vaal Reefs on the quality of effluents after lime treatment to pH9-9.5 indicates that heavy metals and manganese are very efficiently removed by this treatment. Cyanide is also effectively removed and, from the standpoint of toxic metals the approach appears to be very effective especially considering that as much solution as possible is recovered for re-use.

It is known that a South African impoundment lining company has installed activated clay linings for some ponds along the banks of the Vaal River. It is believed that these dams were lined to prevent seepage of raffinate into the river. No precise details were obtained except that they were installed by:

Aquasave (Pty) Ltd.
P. O. Box 68288
Bryanston 2017

Telephone: (011) 789-1206/7
Contact: Chris Lee

The hydroseal-processed bentonite applied at 10 Kg/m^2 results in a less expensive self-sealing lining. It has a higher gel density and gel rate than untreated bentonite and is applied as a layer without mixing into the soil. Aquasave claims that it costs a small fraction of a plastic liner.

South Africa is very concerned about the steady buildup of TDS in the water supply in the Vaal River and appears to be about to modify effluent regulation to prevent discharge of high TDS effluents. It is anticipated that 2-3 years from now there will also be restrictions of some kind on seepage losses of high TDS effluents which could impact groundwater quality. At that time it may prove necessary to examine seepage losses from wasterock piles, tailings dams, evaporation ponds and recycle water storage areas.

It is not known whether the metals precipitated in the effluent treatment plant are amphoteric. In other words, if the tailings dams are abandoned one day, and acid mine drainage results from the oxidation of the pyrite content in the tailings, will the precipitated metals redissolve and leach from the heaps?

CONCLUSIONS

1. Vaal Reefs uses about 1.0 m^3 new water per ton solids treated for uranium and gold recovery, which probably can be further improved.

2. Being located in a climate with a net evaporation it is possible to operate a zero discharge facility - any excess effluents can be evaporated.

3. Vaal Reefs makes an effort to recover as much recycled water as possible for reuse. There are possible losses to seepage from the tailings ponds, evaporation areas, reclaim water ponds etc. which are not lined. The fact that these facilities are underlain by clay-rich sediments does not mean that they don't leak.

4. The effluent treatment plant makes a low metal recycle solution by treating all effluents and tailings with lime to pH 9-9.5. This requires 10-12 Kg lime/t costing about R0.80/t or R7.3 million/year. The question could be asked whether it would not be more effective to separate the low pH raffinate for disposal through evaporation rather than having to neutralize it.

5. A detailed water (and salt?) balance now being prepared will lead to several ideas for further water savings and cost savings.

6. Vaal Reefs is able to recycle some sewage plant effluent to metallurgical processes without detrimental effect on gold and uranium recovery.

INTRODUCTION

The Black Mountain operation near Aggeneys in the northwest Cape Province of South Africa treats a complex sulfide ore to recover copper, lead, and zinc concentrates with important silver values.

Unlike other massive sulfide mills in the Canadian shield, this one is located in an extremely arid climate with one of the highest evaporation rates in the world, where water costs R0.60/m^3 (U.S. \$0.30/m^3).

Several interesting observations have been made by Black Mountain staff in their quest to improve their copper recovery and concentrate grade. These include:

1. Comparison of bulk versus selective flotation results.

2. Impact of recycled water on flotation recovery.

3. Impact of cemented backfill on water quality and hence on flotation recovery.

4. Results of the treatment of recycle water by soda ash to remove calcium and the impact on flotation.

5. The need for aeration and the impact of corrosion of grinding media on water quality/flotation performance.

6. Effect of the use of corrosion resistant balls for grinding on water quality and flotation.

7. Effect of water conservation on operating costs at a location where water is expensive.

PRODUCTION DETAILS

A total of 3,300 metric tons of ore are treated daily for 340 days per year for a total of 1,125,000 tpa by flotation.

LOCATION

In the Kalahari Desert just south of the Orange River in the northwest Cape Province of South Africa near Aggeneys.

CLIMATE

1.9 m (65") evaporation per year. 100 mm (4") rainfall. Extremely hot summers. Cool winters but no snowfall.

ORE CHARACTERISTICS

Minerals to be recovered are chalcopyrite, galena, and sphalerite with associated silver.

Gangue minerals comprise pyrrhotite, pyrite, magnetite, quartz, amphibolite, and other silicates and occasional cement from backfill.

PROCESS

Crushing, grinding, and sequential flotation for recovery of chalcopyrite, galena, and sphalerite in that order. The high Pb:Cu ratio is the reason for choosing a selective float rather than a bulk float; the latter results in poor copper concentrate grade.

The distribution of metals and grades of concentrates were determined by tests done at MINTEK in the Transvaal and in a 2.5 t/h pilot plant at Black Mountain.

Nine reagents are added at up to forty three points for the three flotation circuits with comprehensive automated on-line monitoring by a Courier 300 X-ray analyzer which samples and analyzes fourteen streams for copper, lead, zinc, silver, iron, and solids on a continuous basis. Three process computers are employed with a control center to stabilize and optimize the flotation circuits.

The lead and zinc circuits were quickly brought to design performance, but the copper circuit failed to meet design performance both with respect to grade and recovery. The quality of recycle water appears to have a lot to do with this.

Design product recovery rate for the following tonnages of metal contained in concentrates:

32,000	Tons Copper per Year	68 tpd
134,000	Tons Lead per Year	394 tpd
35,000	Tons Zinc per Year	103 tpd
112	Tons Silver per Year	

The silver reports mainly with the lead concentrate (about 72%) and with the copper concentrate and accounts for more revenue than any other metal. When copper and lead concentrate recovery is optimized, it is found that silver recovery is also optimized.

RECOVERY

	Design	Actual	
Copper	76%	36.9%	At startup.
		57.8%	Change to dichromate adding Z-4, collector paddles installed on rougher cells.
		55.9%	After installing pre-aeration.
		62.9%	Bulk float result.
		67.0%	Aimed for after improving water quality and using corrosion resistant balls.

WATER COST

Water is supplied by a 60 kilometer pipeline from the Orange River. This clarified river water is supplied at a price of R0.60/m^3 by the Pella Water Board which is managed by Black Mountain Mineral Developement Co. Ltd. It is noted that most of the price of this water is to cover the fixed costs of operating the pipeline. Reducing the water consumption results only in a proportionate increase in the unit cost.

The Pella Water Board pays R0.23/m^3 to the Dept. of the Environment for raw river water. Black Mountain's annual water bill for the mill amounts to R900,000 (US$450,000).

WATER DEMAND

14,000-14,500 m^3/d in summer.
11,000 m^3/d average yearround.

WATER USE ALLOCATION

Metallurgical Plant	4,000 m^3/d
Township	4,000 m^3/d
Road Maintenance	500 m^3/d
To Backfill	1,200 m^3/d
To Shaft	800 m^3/d
Cooling, Compressors, etc.	500 m^3/d
Annual Average	11,000 m^3/d

NUMBER OF EMPLOYEES 250 + 500 + 700 = 1,450 total.

Water consumption for the township works out to 2.75 m^3 per person per day which is high by industry standards but includes desert vegetable gardening and the making of a habitable garden environment to attract good staff.

CAPITAL COST - WATER

The Pella Water Board capital cost for clarification, pumping station, and pipeline was R7.00 million ($4.2 million).

WATER RECYCLING

The Black Mountain plant uses 1,500 m^3/d or about 25% reclaimed tailings water. This percentage is dropped further if the 1,200 m^3/d fresh water used in the cement backfill plant is added in. In the water balance of January 19, 1984, a higher percentage of water was recycled. Water recycling has been identified as a cause of poor recoveries.

METALLURGICAL CONSIDERATIONS

GRAHAM AND HEATHCOTE (1982) described the effects of the oxidation state of the pulp on the selective flotation of chalcopyrite from Black Mountain ore. These details and additional later testwork is included in a paper by TWIDLE AND ENGELBRECHT (1984) which is inserted below because it is an excellent illustration of the complicated interrelationship between water quality, physical parameters (e.g., temperature), flowsheet layout, and reagent selection and their impact on metallurgical performance.

WATER BALANCE

A water balance dated January 19, 1984, is shown here which shows an arrangement in which 2,150 m^3/d of water is recycled at a total of 5,500 m^3/d to the grinding circuit or 40% recycle in the grinding circuit. In this water balance, 4,200 m^3/d of the total of 12,000 was fresh, i.e., 65% of the water used in the flotation plant (including reagent mixing) is recycled. However, only 1,400 m^3/d (12%) is reclaimed from the aging pond.

WATER QUALITY

Monthly water analyses for reclaim water and copper tails thickener overflow as received are shown here to provide an indication of the composition of this water.

It is noted that:

1) The calcium hardness of the copper tails thickener o/f water (1,000-1,500 ppm) and reclaim water (1,500-2,000 ppm) is high.

2) Calcium and sulfate levels indicate that the reclaim water is close to gypsum saturation. This is not surprising considering that pyrite/pyrrhotite is oxidized along with some other sulfides to generate sulfates; cement is used in backfill which contributes calcium in the shaftwater that is returned to the tailings dam.

3) Reclaim water contains 400-700 ppm total organics believed to be flotation reagent degradation products.

WATER QUALITY EFFECTS

1. It is noted that 700-1,200 m^3/d of fresh water is consumed in the tailings backfill plant. 950 m^3/d of water recovered from the backfill mixing plant ends up in the tailings pond where it undoubtedly adds calcium to the decant solution in the pond. Black Mountain staff believe that the 500 ppm or so organics in recycled water would result in a weakened cement.

2. The aging pond and tailings dam are shallow ponds in a very hot climate with 1.9 m evaporation and 100 mm rainfall per year. This unquestionably has a concentrating influence on tailings reclaim water. It may also result in clogging of underdrains due to salt (gypsum) precipitation, although these effects are not readily apparent in the reclaim water quality data.

3. When pyrrhotite levels increase, this has sometimes been correlated with copper recovery reductions. This effect is counteracted by the operation of an aeration circuit.

4. A clearcut influence of using more fresh water in the flotation circuit on lead recovery is shown in the graph provided by the Black Mountain staff. What species in the recycled water causes the problem is not completely clear. See 6 below.

EFFECT OF FRESH WATER INCREASE AND IMPROVED WATER QUALITY

5. TWIDLE AND ENGELBRECHT (1984) point out the negative effects on copper recovery of using increased amounts of recycle tailings water irrespective of whether or not the pulp was aerated prior to flotation.

6. Bench flotation tests showed that a decrease of about 10% in the copper recovery was attributable to a cement contamination of 45 Kg of backfill per ton of plant feed producing a pH of 9.8.

7. When the feed pH was increased on account of backfill in the ore, increased amounts of sulfurous acid had to be added with a resulting extremely brittle shallow froth, although the selectivity of rougher flotation of copper versus lead improved when ore was contaminated by backfill.

8. The Redox potential of the pulp has a critical effect on copper recovery, and the EH, in turn, seems influenced by the type of grinding balls and the degree of aeration of the pulp.

9. Treating reclaim water with soda ash to modify pH in the lead circuit and to precipitate calcium from plant water, followed by filtration, improved lead recoveries considerably. Approximately 1.5 Kg Na_2CO_3/t is required at a cost of $0.33/Kg to reduce the calcium hardness of the water from 1,600 ppm $CaCO_3$ to less than 100 ppm in the lead circuit and to 500-750 ppm in the copper tailings thickener underflow.

10. Copper rougher froth quality and recovery was shown to be improved when reclaim water is treated in the same way with Na_2CO_3.

11. Work by MINTEK in Randburg, Transvaal indicated that removal of metal ions (Cu, Pb) and organic flotation reagent degradation products from plant water by activated charcoal would improve the selectivity of flotation when using this treated water. In tests at Black Mountain it was found that activated carbon was successful in removing Cu and Pb and Z-200 collector from recycled water. Tests using this treated water did little to enhance copper recovery or selectivity. Better metallurgy was obtained by diluting reclaim water with 25% fresh water.

12. Copper sulfate consumption in the zinc circuit could be halved when water was treated by Na_2CO_3, to below 100 g/t.

13. When soda ash treatment of water was in use, silver recoveries improved from 82.4% to 83.8%, and lead recoveries improved from 86.6% to 89.1% showing the effect of calcium on the recovery of these two metals which resulted in a net increase in revenue after deducting the cost of soda ash of R60,000/month.

14. When soda ash softening was used in a plant trial, it was found that the moisture content in concentrates increased which would lead to an increased cost of shipping.

WATER TREATMENT PROCESSES

1) Carbon Treatment

Pica carbon C210AS carbon was tested in a column by MINTEK who was able to remove most organics and metals from reclaim water as follows:

	Feed	Treated Solution
Cu	2.7 ppm	Less than 0.5 ppm.
Mn	2.3 ppm	0.5 ppm
Thionocarbamate	12.00 ppm	Less than 0.2 ppm.

2) CO_2 Blowing and NaOH Precipitation

The CO_2 process was able to achieve the following:

	Feed	Treated Solution
Mn	2.3 ppm	0.5 ppm
Ca^{2+}	790 ppm	18.0 ppm
Mg^{2+}	14 ppm	11.0 ppm

TAILINGS DISPOSAL

All tailings are pumped to the backfill plant where the coarser fraction is removed by cyclones for use as backfill. The cyclone overflow is pumped to the tailings dam and distributed to the dam wall at 60 m intervals.

The dam was designed and constructed by Steffen Robertson and Kirsten of Johannesburg and is fitted with piezometers.

Although the operation is located in a very arid region which receives 2-4 inches of rain per year, the tailings dam is provided with a berm which serves as flood protection in the event of a flash flood.

EFFECT OF RECLAIM WATER/AERATION ON COPPER RECOVERY

Introduction

The poor performance of the copper circuit subsequent to aeration was believed to be due to the use of reclaim water and this hypothesis was tested on a laboratory scale.

Procedure

The procedure used was as follows :

Milling : 2 Kg -3mm ore ground with mild steel rods for 37 minutes in a lab. mill at 67% solids with 500g/t $ZnSO_4$.

Flotation Condition 5 minutes with
6 g/t MIBC, 9 g/t Z200 at pH 6,0
Float 3 minutes
Add SO_2 pH6
Float 3 minutes
Add SO_2 pH 6
Float 3 minutes

Some tests were done with reclaim water throughout and some with 30 minutes aeration prior to conditioning as follows :

Test No	1	2	3	4
Water Type	Reclaim	Fresh	Reclaim	Fresh
Aeration	Y	N	N	Y

Results

The results of the tests are appended.

Discussion

Graphs 1 to 3 show respectively the Cu, Pb and Zn recoveries against time for the various conditions.

Graph 1 shows clearly that aeration improves the rate of copper recovery with both fresh and reclaim water, but the curves for reclaim water have a slower rate than for fresh water, with and without aeration.

Graph 2 shows that aeration increases the rate of lead recovery with both fresh and reclaim water and that reclaim water give higher rates of recovery than fresh water.

Graph 3 reveals the expected feature that with no aeration reclaim water gives a higher rate of zinc recovery than fresh water. Aeration increased the rate with both water types but the fresh water gave a higher rate than reclaim water.

Conclusions

Reclaim water has a detrimental effect on rate of copper recovery both with and without aeration.

It would be worthwhile to repeat these tests to determine if the effect is consistent and to quantify the effect on plant results.

SODA ASH PLANT TESTS.

1.0. INTRODUCTION.

Three plant trial tests were done during August/September 1983 to evaluate any benefits which may be obtained by using soda ash (Na_2CO_3) in the lead circuit as a replacement pH modifier for lime, in order to soften plant water to improve froth stability.

2.0. RESULTS.

2.1. A total of 150 tons soda ash was added to the lead conditioner as a ± 10% solution during the three test runs. Mixing and feeding procedures are described in a previous report.

2.2. Water softening was efficient at a dosage rate of 1.5kg/t, reducing calcium hardness from approximately 1600 ppm CaCo, to less than 100 ppm in the lead circuit, with calcium hardness in the copper tailings thickener underflow dropping from 1500 ppm to between 500 and 750 ppm.

2.3. Froth stability improved in all three circuits with a dosage of 1.5 kg/t: an increase to above 2,0 kg/t after steady state conditions had been reached, however, resulted in a shallow, slimey froth.

2.4. Soda ash addition rate could not be adequately controlled by means of the Pb conditioner pH, owing to pH fluctuations in the copper tailings thickener. During the first two runs Pb conditioner pH values of between 9,2 and 9,5 were attained with 1,1 kg/t Soda ash; in the final test, a pH of 8,5 could not be maintained without simultaneous lime addition.

2.5. Copper sulphate consumption in the zinc circuit during the soda ash runs was halved, with consumptions of below 100g/t being intermittently recorded.

2.6. During the third test run, 100 g/t soda ash was added to the rod mill for a period of 24 hours. No additional improvement in copper froth or recovery was apparent, however.

2.7. Daily lead and silver recoveries, together with soda ash consumption, are plotted in figure 1. The time scale extends from 26th to 27th September.

3.0. DISCUSSION OF RESULTS.

3.1. Average lead and silver recoveries during the period plotted were as follows:

Soda ash	off	on
Pb rec. to Pb conc (%)	86.6	89,1
Total Ag rec. (%)	82,4	83,8

Lead and silver recovery increases due to soda ash were thus 2,5% and 1,4% respectively. This includes the period during the third test when over-addition of soda ash led to froth deterioration and hence poor recoveries.

3.2. Based on a 2% Pb and 1,5% Ag recovery increase, a copper sulphate consumption reduction from 800 g/t (average January-August 1983) to 400 g/t, and a soda ash consumption of 1,5 kg/t, an operating costing would be as follows:

Metal prices:	Pb R427 / ton
	Ag R414 / ton.
Head grade:	9,5% Pb; 135 g/t Ag.
Milling rate:	94 000 tpm.

Soda ash (kg/t)	0	1,5
Pb recovery %	88,0	90,0
Ag recovery to Pb conc. %	70,0	71,5
Pb conc. % Pb.	70,0	70,0
Pb conc. g/t Ag	791	790
Tons Pb conc. pm.	11226	11481
R/ton conc.	360	360
Revenue from conc. (R pm)	4 041 360	4 133 160
Revenue difference (R pm)		+ 91 800
Cost of soda ash (R pm)		56 400
$CuSO_4$ cost reduction (R pm)		25 200
Nett revenue increase (R pm)		60 600

3.3. The potential increase in revenue derived from better copper and zinc metallurgy owing to better froth stability and circuit control cannot be assessed at this stage.

3.4. The only disadvantage in using soda ash established during the test periods was a deterioration in concentrate moistures (particularly copper and lead). Addition of lime to the concentrate thickeners and increased filter aid addition did not improve cake moisture: implementation of concentrate heating prior to filtration may prove necessary.

BULK STORAGE, MAKE-UP AND FEEDING OF SODA ASH

EQUIPMENT

The following equipment would be required for a system to receive, handle and feed Soda Ash as a 10% strength solution to the lead conditioners, at a consumption rate of 1,5 kg/ton treated.

200m³ storage silo 230 tons @ 1,16 ton/m³

Gate valve

Rotary feeder (A) 40 kg/min

Screw feeder 40 kg/min

Measuring flask 0,6m³ @ 1,02 ton/m³

Rotary feeder (B) 120 kg/min

1 Automatically controlled valve (C)

0,3m³ conical bottom mixing tank

Agitator plus drive for mixing tank

2 x Transfer pumps 200 l/min each

40m³ Storage tank

Agitator plus drive for storage tank

2 x Delivery plus 50 l/min each

8 Valves (Saunders type)

5 Level Probes (HA, H, L, HH, LL)

Spillage retaining wall + Spillage pump

Vibrator unit

All steel work to be rubberlined.

MAKE-UP

A cycle would be as follows :

Add fresh water 400 l/min Weigh Soda Ash 40 kg/min	15 minutes
Charge Soda Ash 120 kg/min	5 minutes
Mix Soda Ash	10 minutes
Transfer batch 200 l/min	30 minutes

Daily consumption would be 5 to 6 tons of Soda Ash so that 8 to 10 batches per 24 hours would have to be mixed.

This could either be done entirely on the morning shift or continuously throughout the day, the latter arrangement probably being more suitabale.

By the use of level probes and a programmed sequence the mixing and transfer functions could be done automatically.

2/.....

REQUIREMENTS

It should be possible to resite one of the cement storage silos at the backfill plant for use as a bulk storage facility.

A 6,8m³ tank is available in the reagent mixing bay that is presently not being used, as well as an agitator shaft.

The screw feeder and measuring flask could be made at the concentrator and the second line ring main would serve as a feeding system.

All other equipment would have to be purchased.

T B [illegible]
Plant Superintendent

13th September 1983
/jr

BULK STORAGE, MAKE-UP AND FEEDING OF SODA ASH

The tailings dam is fitted with a blanket drain to drop the phreatic level in the tailings. It also is fitted with a decant tower. Flow from the decant tower and the blanket drains go through the tailings dam wall in pipes and then flow via an open ditch by gravity to a two compartment aging pond.

Drainage and decant from the tailings dam all flow into one ageing pond. Decant from the ageing pond is pumped back to the mill return water tank at the plant.

CONCLUSIONS AND DISCUSSIONS

1. Water quality of reclaimed solution may be improved if the surface area of the impoundments could be reduced or protected in other ways from evaporation which undoubtedly results in an increase in TDS of the reclaimed water.

2. At comparable bulk-float plants in Canada it has also been found that reclaim water upsets the selectivity of copper flotation in the presence of lead.

3. Aeration as a conditioning step has been found to be important in Canadian complex-sulfide plants, just as in this case.

4. Presence of calcium in water was found to cause a brittle froth with reduced copper recovery and reduced selectivity and also an important drop in silver recovery. This was overcome by treating reclaim water with soda ash to precipitate calcium carbonate which could be removed by filtration.

   Considering the high sulfate and virtually saturated gypsum content of the reclaim water and also the inverse solubility versus temperature relationship of gypsum, it is possible that froth embrittlement is caused by precipitation of gypsum in the froth.

   It would be very interesting to observe the effect on flotation results if, instead of adding soda ash, reclaim water was treated by seeded slurry R. O. to remove the whole spectrum of dissolved solids. Final pH adjustment might be achieved with soda ash or sodium hydroxide.

5. It is observed that fresh water is added to backfill tailings and cement mix. Water recovered from this step is returned to the tailings dam. If a way could be found of mixing backfill without needing fresh water and using reclaimed water, then the extra fresh water could be used in the flotation plant.

It was pointed out that reclaim water containing organics causes a weakened backfill. Were these backfill strength tests performed on reclaim water at the startup of the operation when ore contained large amounts of grease from the startup mining operation? Backfill practice and strength might be compared with other operations (e.g., Noranda Geco, Mattabi, and Kidd Creek Mines) which also employ backfill.

6. In Canadian complex sulfide mills SO_2 is also found necessary. In most cases, sulfurous acid is added directly in the mill itself. At one mill it is added after being mixed with NH_4OH. Possibly the same could be tried at Black Mountain. SO_2 is used in copper flotation.

7. Copper tailings thickener overflow water, which is added to the mill return water tank, appeared to be relatively high in suspended solids. The affect this has on flotation recovery or reagent consumption was not determined.

8. Considering the high rate of evaporation, it is to be expected that the solution in the exposed tailings dam would become increasingly concentrated due to the loss of water. For this reason it would be expected that gypsum or other salts may one day foul the blanket drain in the tailings plant. It is not known whether this will occur nor what can be done about it, if it does.

OPERATION FALCONBRIDGE NICKEL MINES LTD.
SUDBURY OPERATIONS
FALCONBRIDGE, ONTARIO
CANADA POM 1S0

CONTACT John K. Weglo — Director Environmental Control

R. E. Michelutti — Senior Environmental Biologist

INTRODUCTION

Falconbridge mines, mills, roasts, smelts and refines nickel and copper on a large scale at their operations at Falconbridge, Ontario in the vicinity of Sudbury. In all 1800 tpd of sulfide concentrates are roasted and treated at the Falconbridge site. These concentrates are produced at the Falconbridge site and by the mines and a mill at Onaping about 25 miles north of Sudbury.

A complete description of the Falconbridge operations dealing with all aspects of environmental control that relate to water management, directly and indirectly, would make a very long and complex story but an interesting one.

Here, some of the more interesting highlights are reviewed:

1. Impact of changing the pyrometallurgical processing steps on water quality.

2. Designing and applying a systems approach which integrates management of water with the mines, mills and metallurgical recovery processes as well as wasterock, mill tailings, local municipal garbage, and sewage sludge disposal.

3. A most impressive use of a natural bog as a polishing step in treating recycled water and seepage from mill tailings.

4. Observations and recent improvements in housekeeping which avoid former impact on water quality.

5. Interception of contaminated groundwater which is pumped to the mill for use as process water.

6. Important observations as to where to apply lime neutralization in the water recycling loop.

VIEW OF SUDBURY BEFORE MINING STARTED
LOGGING & FIRES HAD DENUDED THE LANDSCAPE

PRODUCTION CAPACITY

Falconbridge mills 2000 tpd ore at Falconbridge and 7-8000 tpd at Onaping to produce 70,000,000 lbs nickel per year at current production.

LOCATION At Falconbridge, Ontario in the outskirts of Sudbury.

CLIMATE Mild summers with rainfall exceeding evaporation. Long frozen winters with heavy snowfall typical of the Canadian Shield.

ORE TYPE

The ore contains iron, nickel and copper primarily in the form of pyrrhotite, pentlandite, chalcopyrite. In addition to nickel and copper a number of other metals - cobalt, selenium, silver, platinum, palladium, rhodium, iridium and ruthenium are recovered from the ore. Common gangue minerals are feldspar, quartz, mica, talc and chlorite. The dominant sulfide mineral is pyrrohotite, Fe_7S_8 carrying 0.2-1.2% nickel. Falconbridge ore averages 25% pyrrhotite and 2-3% pyrite.

METALLURGICAL PROCESSES

Ore is crushed and ground to 60% minus 200 mesh and floated to recover a copper-nickel concentrate product by bulk flotation and a pyrrhotite concentrate that is discarded with the tailing slimes. The nickel-copper concentrate assays about 12% Ni + Cu and contains over 90% of the pentlandite and the chalcopyrite.

Flotation reagents used include sodium isopropyl and potassium amyl xanthates and a frother, either triethoxybutane or polypropylene glycol ether. Copper sulfate is used as an activator for the slow floating pyrrhotite; lime, soda ash and sulfuric acid are used for pH control. The Cu-Ni concentrates are roasted in a fluid bed roaster followed by smelting in electric furnaces. The melt is blown to remove iron and a copper-nickel matte produced for further electrolytic processing in Norway following a chloride leach.

TAILINGS TREATMENT

Tailings are deslimed using hydrocyclones and the coarse sand fraction pumped underground as backfill. Tfhe finer slimes are discarded to impoundment areas equipped with retaining dams and decant towers which overflow to the treatment plant. On average, 0.5 tons tailings is backfilled per ton of ore hoisted. The tailings sandfill plants incorporate both stirred and settled storage and also cement receiving and mixing facilities.

IMPACT OF CHANGING PYROMETALLURGICAL PROCESS

Earlier companies employed huge open roast yards (1888 to 1927) where the ore was roasted outdoors utilizing wood as fuel. Sulphur content in the ore was reduced from 25% to 7-10% with this method. Dense SO_2 clouds were given off at ground level for several months during each roast yard burn. Falconbridge Limited, incorporated in 1928, employed a tall stack at the outset. By the 1950s this process had been replaced by a sinter plant and a blast furnace. 80% of the sulfur was emitted to the atmosphere.

Since 1953 wet magnetic separation has been inserted into the flotation circuit to remove phrrhotite and further reduce sulphur emitted to the atmosphere. By 1960, only 50% of the sulphur was emitted to the atmosphere. In 1972, a $78 million nickel-iron refinery was built to further reduce SO_2 emissions by producing elemental sulphur. Technical problems and difficult financial times resulted in the closure of this plant. In 1978, a new smelter and acid plant were constructed for $85 million, again to improve the working environment and reduce emissions.

By 1982, improvements had been made to the acid plant and by installing fluid bed roasters and electric furnaces to replace the sinter plant and blast furnaces, only 16% of the contained sulfur was emitted. By 1984 further improvements had reduced the amount of sulfur emitted to 11% of that in the plant feed. From 1800 tpd of feed concentrate roasted, only 225 tpd of SO_2 is released.

The new smelter also reduced airborne nickel emissions by 94% and copper by 89%. Particulate emissions (7-8% Ni) were reduced from 17.0 tons/day to 1-2 tons/day.

Falconbridge Limited, coupled with Inco's environmental improvements over the years has resulted in improvements to the Sudbury area soil, lakes and vegetation.

50 Sudbury area lakes between 1974-6 and 1981-3 have had the following improvements:

89% of the lakes decreased in copper levels
75% of the lakes decreased in nickel levels
100% of the lakes decreased in sulfate levels.

Because of the historic lumbering, followed by processing of ores and concentrates, the soils in the Sudbury area had become acidic. Due to environmental improvements by both companies, the pH of soil in the area has started to increase. pH continues to be affected by snow and rain on the area with a low pH of around 4.3 and it is pointed out that SO_2 and NOx from the USA is a major contributor to the acid rain problem.

One way of reducing SO_2 stack emissions has been to separate the pyrrhotite and discard it to tailings where it potentially will generate acid. This appears as a trade-off with air pollution versus water pollution. Water pollution is, however, easier and less costly to control. Air pollution also leads to water pollution spread over a larger area.

Since cleaning the roaster gas there has been an improvement in water quality with respect to sulfate and nickel levels in the surrounding area lakes.

Improvements to the acid plant and resulting environmental improvements at Falconbridge are discussed in detail by NORMAN & MICHELUTTI which is inserted below.

Designing and Applying a Systems Approach

Removal of SO_2 and particulate materials from the gas emissions reduced the distribution of sulfates, Ni and copper to the general environment. This has had a significant impact on water quality and is just one part of an overall systems approach adopted at Falconbridge, some of which is described by NORMAN & MICHELUTTI. Some additional details are worth noting. The systems approach must cater to collecting and treating AMD from the tailings areas, inhibiting AMD and treating AMD to make it suitable for reuse and for discharge as an effluent.

EFFLUENT DISCHARGE

5480 Igpm or 37,000 m^3/d was discharged to Coniston Creek in 1979-80. Falconbridge's climate constraints make zero discharge an impossibility.

WATER TREATMENT

Average flow through the treatment plant in 1979-80 was 2511 Igpm (16,000 m^3/d). The aeration and lime addition plant is described by NORMAN & MICHELUTTI. Following precipitation the treated water is settled in a settling pond with 15 day retention, capacity of 286,000 m^3 and 0.63 km^2 area. A polyelectrolyte is added to accelerate the settling of precipitated solids. Capital cost of the water treatment plant was $257,000 in 1978.

Operating costs of the water treatment plant were C$104,600 in 1979 (1.8¢/$m^3$) and C$60,100 (1.0¢/m^3) in 1980 which works out to 4.6¢ per thousand gallons treated.

The reduction in costs in 1980 was due to reduction in lime consumption costs after lime addition was automated.

1970

How to establish vegetation on

By R. MICHELUTTI
Falconbridge Nickel Mines

The ore in the Sudbury Basin consists of a number of sulphide minerals composed predominantly of nickel, copper and iron with various other minor but valuable elements. To separate the valuable minerals from the gangue, the ore is crushed and ground to at least a fineness of 100% – 48 mesh. The copper-nickel sulphide minerals are separated from the gangue minerals by a combination of flotation and wet magnetic separation processes.

Three products result – a copper-nickel concentrate that is sent on for further processing, a pyrrhotite (iron-sulphide) concentrate that is either stockpiled or disposed of, and the tailings. Although consisting predominantly of silicate minerals, the tailings do contain minor amounts of sulphide minerals and a typical analysis will show about 0.85% sulphur. The pyrrhotite concentrate contains about 36.5% sulphur and 56.0% iron.

The relatively coarse tailings fraction, above 25 microns, amounting to about 70% of the total is separated by cycloning and returned to the mine for backfill. The fine tailings or tailings slimes, generally minus 25 microns in size, is discarded, either separately or mixed with the pyrrhotite, to tailings disposal sites.

A ton of average grade Sudbury ore produces 200 lbs of concentrate, 800 lbs of tailings backfill, 500 lbs of pyrrhotite and 500 lbs of tailings slimes. Thus, half of the ore mined consists of waste products that may be disposed of on surface. If possible, land-locked basins or lakes are selected as tailings disposal sites, but if such natural depressions are unavailable the tailings slimes must be contained behind artificial dams.

Falconbridge Nickel mines over 4 million tons of ore annually and therefore each year has to dispose of some 2 million tons of tailings slimes and pyrrhotite, which occupy a volume of over 35 million cubic feet.

Seepage

When a tailings disposal area reaches its designed capacity and is abandoned there are liable to be three major problem areas, acidic seepage or run off, dust and aesthetic appeal. A properly designed and maintained tailings disposal area will minimize the problem of acidic seepage and run off, however, it is unlikely that it can be completely eliminated.

The material constituting tailings is by its very nature a dust, and large areas denuded of vegetation may be picturesque in some locations on our planet but they cannot be considered as attractive features on the wooded landscapes of north-central Canada.

During the life of the tailings pond, water is continually seeping through it and becoming contaminated with iron and various metal sulphates. Because of the fine particulate nature of the tailings, the constituent minerals present a tremendous surface area, making them extremely susceptible to leaching and other chemical reactions.

Where sulphide minerals are present, sulphuric acid is generated, and depending on the amount of sulphides and the composition of the gangue minerals, the pH of the seepage effluent may be in the order of 3.0 or lower and if the volume is sufficient the downstream ecological environment may be seriously endangered.

Dust storms

Once a tailings pond has dried up, the fine particles easily become windborne. This, coupled with the flat topography of tailings areas, results in severe dust storms, even at moderate wind velocities. Since the dust contains metallic salts and is easily dispersed throughout the adjoining area, widespread contamination of a watershed may result.

If residential areas or manufacturing industries are located nearby, the dust will present both a serious nuisance and increased problems and costs in the maintenance of machinery and equipment.

Although mining operations are usually located in remote areas, this is not

1971

1972

high iron-sulphur mine tailings

always the case, and even so, with our increasing awareness of the necessity to preserve wilderness areas for recreational purposes, the past practice of merely abandoning tailings areas without any attempt to restore them to their natural state is no longer acceptable.

Stabilization of tailings

Abandoned tailings areas must be stabilized to reduce or eliminate the problems previously mentioned. Various methods have been employed to reduce these problems, but most fail to eliminate all of the problems. Dust problems, for example, may be solved by placing an overburden of crushed slag, rocks or gravel on the tailings. This will not, however, reduce seepage or improve the appearance of the area.

Water cover

Another method is to completely cover the tailings area with water. Provided that dams are properly constructed to stop seepage this method will solve all three problems. The only disadvantage is that the area must always be maintained to ensure that dams won't fail and that the water cover remains. Once a mining complex becomes inoperative maintenance will normally cease and it is only under particular circumstances that this method could be acceptable.

Other methods, such as chemical stabilization with asphalt or polymers to produce a layer impervious to both air and water, also have the disadvantage of requiring maintenance. Furthermore, with this type of cover, the aesthetic quality of the area is hardly likely to be improved.

The obvious solution to the problem, if it can be achieved, is to restore the terrain to some reasonable semblance of its natural state by providing a cover of vegetation over the tailings. This method restores the aesthetic value and may even improve on the intrinsic value of the property.

Revegetation prevents the material from becoming windborne and will restrict, even though it may not entirely eliminate seepage. Also, with time, the endemic species will encroach to make the area self-sustaining.

The establishment of vegetation on tailings, unfortunately, is not a simple task, for the following reasons:

- Tailings are unsuitable as a soil for supporting plant life for a number of reasons. The material has a poor structure lacking in aggregates. Tailings are almost entirely deficient in nutrients and in an ion exchange capacity. Proper bacterial communities are absent, and toxic concentrations of heavy metals may be present.
- Because of the extremely fine particulate nature of the tailings, dewatering takes a long time and the area remains an inaccessible bog long after the surface has dried. Specialized machinery may therefore be needed to attempt the revegetation operation.
- Since the areas are large flat expanses composed of very fine particles, dust storms are common and for this reason it is essential that the entire tailings area be stabilized at one time. Otherwise established vegetation can easily be destroyed by sandblasting or burial by the unstabilized material. If it is not practical to vegetate an entire tailings area at one time it will be necessary to provide some form of temporary stabilization to the unvegetated portion.

Nickel Rim mine tailings

Nickel Rim Mines operated a mine and concentrator between 1952 and 1958 on a property located at the east end of the Sudbury Basin approximately 7 miles north of the town of Falconbridge. During these years, some 35 acres of land were covered with tailings.

In the Nickel Rim concentrator operation, no attempt was made to recover pyrrhotite which was discarded with the tailings. Neither was any tailings used for mine back fill at this operation so the material discarded consisted of approximately two-thirds silicate gangue minerals and one-third pyrrhotite.

Although the silicate gangue is inert the pyrrhotite is highly reactive (8)

times more so than pyrite), and under certain conditions spontaneous combustion will occur at room temperature.

$$3\ FeS + 5\ O_2 \rightarrow$$
$$Fe_3O_4 + 3\ SO_2 + 1.9 \times 10^3\ K.\ cal.\ lb^{-1}$$

Even when mixed with tailings the heat produced by the oxidation of the pyrrhotite, where any segregation has occurred, will be sufficient to prevent the growth of any vegetation.

The present surface of the Nickel Rim tailings, from 1 in. to 5 ft in thickness, is a reddish brown colored mass of hydrated iron oxides. Greater than average concentrations of iron and sulphur are present in this oxidized surface layer because of capillary action which brings dilute salt solutions from the interior of the tailings mass to the surface. Subsequent loss of moisture at the surface due to evaporation results in a build up of metallic salts. (Table 1)

The iron and sulphur accumulating at the surface produces a complex matrix known as a "ferruginous cap". This ferruginous cap may become as hard as concrete and virtually impossible to vegetate.

Another barrier to overcome in establishing vegetation on tailings which contain pyrrhotite is the production of sulphuric acid. Polythionates reacting with ferric sulphide result in the production of sulphuric acid which lowers the pH in the oxidized layer (Table 1) to values that are intolerable to any form of vegetation.

$$Fe_2(SO_4)_3 + FeS_2 + H_2O \rightarrow 3\ FeSO_4 + 2\ S\ (7)$$

$$S + 3\ O + H_2O \rightarrow H_2SO_4$$

In 1964 Falconbridge purchased the Nickel Rim property to acquire the considerable amount of low grade ore that had not been mined. At the time pollution was not a serious concern but with changing conditions, Falconbridge subsequently became aware that it had not only purchased some low grade ore but also a pollution problem of considerable proportions.

Unique problem

Although the techniques for establishing vegetation on tailings piles of silicate minerals were well known, nothing had ever been done with the high sulphur content (pyrrhotite) tailings such as those at Nickel Rim. Falconbridge, therefore, found it necessary to embark on a research program with the objective of determining whether the establishment of a permanent cover of vegetation could be accomplished economically on this type of tailings.

This report is a summary of the research work performed by Falconbridge to date in its attempts to vegetate this troublesome area.

Research summary

Research on the vegetation of acid mine tailings commenced September 1970 by the Industrial Wastes Control Department at Falconbridge. Initial tests were conducted in a growth chamber to determine first of all whether plant life could be made to grow at all on oxidized high iron-sulphur and acidic mine tailings. The most economical neutralizing agent and fertilizer requirements had to be determined as well as the plant species that are best adapted to this environment.

Because of limited space in the growth chamber only one or two parameters could be investigated during each test.

TABLE 1 – ANALYSIS OF NICKEL RIM TAILINGS

	Upper Oxidized Layer	Lower Unoxidized Layer
Magnesium	4.25 %	6.4 %
Sodium	.16 %	1.64 %
Potassium	.41 %	.74 %
Calcium	4.44 %	5.53 %
Aluminum	2.3 %	3.2 %
Sulphur	6.23 %	2.31 %
Nickel	.05 %	.220 %
Copper	.031%	.063 %
Zinc	.003%	.0128%
Cobalt	.041%	.03 %
Iron	27.9 %	12.7 %
pH	3.0	4.5

Since any solution to the problem had to be economically viable, it was fundamental that in conducting the experiments the materials utilized would be locally available at a reasonable cost.

Neutralization

The initial series of experiments was set up by Fedko and Michelutti (1) to determine whether the acidity of the tailings could be neutralized by the application of agricultural limestone ($CaCO_3$) and/or lime (CaOH) and also whether a commercial grade fertilizer (10-10-10) would provide the nutrients required to sustain plant growth.

Slightly acidic alluvial sand from the Falconbridge area served as a control. Plant species for these tests were chosen from varieties suited to local climatic conditions and on proven ability to withstand acidity and drought, as well as their availability.

From these preliminary tests it was quite apparent that lime and/or limestone were essential for plant growth on acid tailings. The more agricultural limestone or lime applied to the tailings, the greater the plants' longevity, (Fig. 1).

In the initial experiment all plants died within 30 days but the length of survival was directly related to the amount of neutralizing agent provided. Since both lime and limestone produced similar results on plant vigor and longevity, the lime was discontinued because of its corrosive nature and its potential to produce a toxic alkaline soil by over liming.

No conclusions as to the suitability of the fertilizer utilized in the experiment could be drawn since all the plants died because of insufficient neutralizing agent. However, the control sand pots did indicate the best application rate for 10-10-10 fertilizer to be 1/2 ton per acre.

Optimizing limestone

Having determined that limestone was essential, a second set of experiments was designed and undertaken to determine just how much would be required to ensure plant survival. For these tests the fertilizer content was maintained constant at 1/2 ton per acre.

In January 1971, Hulley set out to determine the appropriate limestone requirements for Nickel Rim mine tailings. Besides limestone content, the advisability of using a straw-asphalt mulch cover was also tested. Although the duration of the test was restricted to a two month period, positive results were achieved as all plants survived during this period.

It was determined that for the Nickel Rim tailings an initial dosage of 10 tons of limestone per acre would be required. The test also showed that a straw mulch cover resulted in greater yields than no cover on both the sand control pots and the tailings pots, with all other conditions being equal. (Fig. 2)

Now that the appropriate limestone content had been determined and it had been shown that a mulch cover of straw-asphalt was beneficial, it was decided that the next step should be to perform experiments in the field to test the validity of the laboratory results.

In May 1971, Langford set up field tests using a randomized block design. Test plots were established on alluvial sand, inactive low iron-sulphide Falconbridge tailings (12% Fe, 1% S), and Nickel Rim mine tailings. The alluvial sand and Falconbridge tailings were to act as controls. Unfortunately the test plots on the Falconbridge tailings were mostly covered and destroyed by

blowing dust in a matter of only two weeks time.

So that there would be a basis of comparison with the lab tests the fertilizer (10-10-10) was still maintained at 1/2 ton/acre on all the plots. The agricultural limestone (not more than 40% + 100 mesh), was applied at 10 tons per acre on both tailings areas and at 4 tons per acre on the alluvial sand. These tests were, therefore, an attempt to duplicate in the field what was felt to be the proper fertilizer and limestone application, based on the laboratory tests.

Because of the success obtained in the growth chamber with a mulch cover, it was also decided to test various mulches in the field. The mulches tested were: straw-asphalt, curasol (a polymer dispersion material), and a 2 in. soil cover. At the same time, 16 different grass and legume species were tested, in a block design, under each mulch cover. Data accumulated between May and October was analysed by Langford (3) in March 1972, with the following conclusions.

- The plant species best suited to the acidic tailings were: fall rye, bromegrass, red top, colonial bentgrass, creeping red fescue, sheep fescue, sweet clover, alfalfa and white clover.
- The mulch covers all proved to be superior to no cover.
- The greatest differences in mulch covers appeared in the test plots on the Nickel Rim tailings where a 2 in. soil cover resulted in a healthy vegetation growth compared to the other plots on these tailings where the growth was stunted and had a high mortality rate. The exact reason why this plot was successful it still not known since the soil became very acidic with a pH of 3.5 in the space of a months time. Perhaps the soil contains a greater ion exchange capacity, beneficial microorganisms, or the micronutrients required by the plants which the fertilizer does not provide. Root studies the following year showed that the roots tended to fan out a great deal in the soil cover before eventually penetrating the tailings. Perhaps this soil cover helps to establish the young plants when they are most susceptible to adverse conditions and upon maturing their root systems are then able to invade the inhospitable high iron sulphur tailings.
- The physical grade of the limestone is very important in affecting a pH change since it must be solubilized to be effective. In one test plot that was treated with 50 tons/acre of a coarse limestone (80% + 10 mesh) compared to the finer grade (60% – 100 mesh) normally used, the seeds all failed to germinate. Even after a six month observation period, there was no growth on this particular test plot.

Fig. 1 Effect of limestone on Timothy in tailings

Fig. 2 Effect of straw asphalt mulch on legumes

Fig. 3 Comparison of topsoils

The results of this initial field test work with the Nickel Rim tailings gave some hope that vegetation could not only be established but also maintained on this type of highly oxidized acidic tailings.

The next series of tests by Gaylor (4) set out to determine the best locally available soils for use as a cover and the optimum thickness of application. The soils were spread in 1 in., 2 in., 4 in. and 6 in. layers and not mixed at all with the underlying tailings. This was done in an attempt to reduce metallic salt concentration at the surface by applying soils having a lesser capillarity rate than the tailings.

Four locally available soils ranging from sand to loam were selected for testing in the growth chamber. 10 T/acre of limestone with 1/2 T/acre of fertilizer was applied on top of the soils. After two months, yields were determined and black loam at a 6 in. depth proved to be superior to the other soils. Even a 1 in. to 2 in. layer of black loam showed a definite improvement in plant growth over any of the other soils. (Fig. 3).

Tests conducted by Cyr (5) on soil properties had demonstrated that a loamy soil has a lower capillarity rate than sandy soils. This, coupled with the fact that black loam has a greater cation exchange capacity (8), could account for the increased yield.

A significant result was that the legumes did far better in these tests than any previous growth chamber tests, and appeared healthier than the grasses for the first time. A good legume catch is very significant in establishing vegetation over long periods of time because of their ability to fix atmospheric nitrogen in the soil.

Fig. 4 Fertilizer application rates of three best fertilizers tested.

Fertilizer types

Up until this time, the fertilizer used

had been exclusively 10-10-10 N-P-K because it was readily available. Cyr (5), therefore, set out to determine whether there might be a better fertilizer to use for establishing vegetation.

Fig. 5

Five fertilizers were studied: CIL 10-10-10, CIL 6-9-6 50% U.F., CIL 12-4-8 66% U.F., CIL 15-5-10 40% U.F. and CIL 2-1-2 sheep manure.

The slow release fertilizer, 6-9-6 50% urea formaldehyde, performed the best at 3/4 T/acre (Fig. 4). The original 10-10-10 at 1/2 T/acre produced much lower yields during the 10-week duration of the experiment and over a longer period of time might have shown even greater differences. A significant observation, as shown in Fig. 4, is that an excess of fertilizer stunts plant growth and is more harmful than no fertilizer at all.

This situation has been termed physiological drought and exists when water is plentiful but a greater osmotic pressure results in the soil because of the high salt content compared to the plants roots. Water will then leave the plants to reduce the pressure gradient created and in this way the plants dehydrate. As previously mentioned, legumes are important as soil enrichment agents, and once properly established the fertilizer requirements may then be substantially reduced.

The field plots set up by Langford during May 1971, were examined by Johnston (6), Oct. 1972, for legume root nodules (Fig. 5). Preliminary observations showed that alfalfa has more nitrogen nodules than sweet clover and that legumes growing in the 2 in. soil cover have much better nodulation than legumes growing directly in the tailings.

The plants on the soil cover had most of their root structure fanning out in the soil with portions penetrating down into the tailings. Most of the nodulation in these plants occurred in the upper root zone growing in the soil cover. This is probably attributable to a proper bacterial ecology in the soil cover, especially the nitrogen producing bacteria, nitrosomonas and nitrobacter which oxidize ammonia to nitrate.

Even though good nodulation was observed in some plants, none had the characteristic healthy pink coloration. The pink coloration is hemoglobin produced symbiotically by the bacteria and legume. More tests are therefore necessary to determine if these nodules are adequate for soil enrichment or if healthier nodulation can be induced by innoculation with the appropriate bacteria. Tests are now under way to determine the effects of innoculation on legumes.

From all the data accumulated over the past two years, some basic conclusions can be made at this time on the vegetative stabilization of the acidic high iron-sulphur tailings at Nickel Rim.

Conclusions

- The tailings area should be first covered with a 4–6 in. layer of the best locally available soil. If this soil is low in organic content, it should be supplemented with sewage sludge, manure or loam. This should reduce the rate of salt build-up at the surface as well as increase the cation exchange capacity.
- High grade fine pulverized agricultural limestone (60%-100 mesh) at 10 T/acre should then be applied to the soil cover.
- 6-9-6 50% U.F. fertilizer should then be applied at a rate of 3/4 T/acre. The slow release factor of the fertilizer will help sustain the plants for the maximum possible period of time without maintenance. Instant release fertilizers can dissolve and wash away during periods of heavy rain fall and may therefore be largely wasted.
- The seed mixture to be used on these tailings is: fall rye, bromegrass, red top, colonial, bentgrass, creeping red fescue, sheep fescue, sweet clover, purple alfalfa, and white clover. For all the test plots rye was maintained at 60 lbs/acre and the other seeds were applied at a combined total of 90 lbs/acre.
- Finally, a mulch cover of straw is extremely beneficial in protecting the young seedlings. This will however, greatly increase the cost, and further work is necessary to determine whether the extra expense is justified.

The research performed to date has resulted in a far better understanding of the problem of establishing vegetation on highly acidic iron-sulphur tailings. The effectiveness of this method in establishing a permanent cover of vegetation that will require little or no continuing maintenance has still to be determined. Also to be determined is whether a cover of vegetation will reduce the seepage from the tailings areas sufficiently to prevent or reduce to acceptable proportions the contaminants that get into the adjacent surface drainage systems. Only by continuing lab and field test programs may it become possible to find answers to the particular questions and problems which arise when attempting to vegetate troublesome areas.

WASTEWATER TREATMENT SYSTEM AT

FALCONBRIDGE ONTARIO

R.E. Michelutti
Environmental Department
Falconbridge Nickel Mines Limited
Canadian Nickel Division
Sudbury Operations
January 1981

Introduction

The new tailings area and wastewater treatment system at Falconbridge was put into operation during the latter part of 1978 at an approximate cost of 3 million dollars. This report summarizes the data and chemical results for this treatment system during the first two years of operation.

Summary

1. The tailings and polishing ponds required 13 weeks to fill to their respective operating levels, for a total of 368 x 10^6 Imperial gallons.

2. The settling pond downstream of the neutralization plant has a retention time of approximately 15 days at 2,900 I.G.P.H. inflow, with a volume of 63 x 10^6 Imperial gallons.

3. The average flow leaving the treatment plant during 1979-1980 was 2,511 I.G.P.H. The total average flow being discharged to Coniston Creek was 5,480 I.G.P.M. during this period.

4. Sulphate concentrations decrease with distance from the source.

5. pH values are 3.5 during summer months and 6.5 during winter in the tailings ponds. This is due to varying oxidation rates of sulpho-salts by chemical and or bacterial action.

6. Nickel concentration in the wastewater inflow dropped considerably from 1979 to 1980. (0.7 ppm to 0.1 ppm respectively).

7. Dissolved nickel concentrations increase downstream from the inflow as well as downstream from the treatment plant.

A possible explanation is the solution pickup of nickel from the bog area.

8. The suspended solids 2 year average leaving the settling pond was 5.8 ppm, indicating that a clarifier is not warranted. It will require approximately 65 years to accumulate 1" of sludge in the settling pond at the present rate of deposition. In fact, this rate will decrease with the mining out of Falconbridge Mine in approximately 8 years.

9. pH depression caused by organic acids in the bog area downstream of the treatment plant was corrected by discharging excess lime.

10. The treatment plant treated 3.6 x 10^6 I.G.P.D. at a cost of 4.6 cents per 1,000 gallons during 1980. On average, 0.84 tons of hydrated lime/day were consumed during 1980.

11. Treated alkaline wastewater has resulted in a rapid colonization of the denuded bog by aquatic plants and wildlife. As a result, the area has been designated a "Conservation Area".

1. Physical Data

1.1 Pond Elevations and Volumes

1.1 (a) Tailings Pond

Wastewater commenced flowing into the new tailings area on August 21, 1978 at approximately 1,500 I.G.P.M. (Figure 2) The water level behind dam #6 rose from 941.7' to 959.4' in nine weeks time. (Figure 1) Based on an inflow rate of 2,808 I.G.P.M. the tailings pond volume is 255 x 10^6 Imperial gallons.

Wastewater Treatment System at
Falconbridge Ontario
Page 2A

FIGURE 1 - POND ELEVATIONS

FIGURE 2
FALCONBRIDGE AREA
Wastewater Treatment System

Contributing to this inflow are the following estimated flows: (Reference 1)

(a) 1,566 I.G.P.M. - Tailings and Process Water

(b) 500 I.G.P.M. - Ground Water

(c) 742 I.G.P.M. - Precipitation

1.1 (b) Polishing Pond

The polishing pond water levels rose from 941.1' to 954.2' in four weeks time. At the above inflow rate of 2,808 I.G.P.M. this represents 113 x 10^6 Imperial gallons.

Water levels fluctuated considerably during 1979 and 1980 coinciding with rainfall and spring freshet. (Reference 1) During January, February and March of 1980 the water level in both ponds was intentionally lowered, in order to accommodate the spring flows. (Figure 1) Even though both ponds are designed to accommodate a Timmin's storm (7.61 inches in 12 hours) this procedure allows the containment of a Timmin's storm coupled with a spring snow melt. A snow melt is 1.1 inches in 5 hours. (Reference #6)

1.1 (c) Settling Pond

The settling pond area was increased during 1980 by extending the slag berm several hundred feet. This resulted in a pond area of 155 acres versus 115 during

1979, or a 35% increase in size. At an approximate depth of 1.5 feet this represents 63 x 10^6 Imperial Gallons. The retention time of the settling pond at 2,808 I.G.P.M. is therefore 16 days.

1.2 Flows

Flows leaving the treatment plant averaged 2,900 I.G.P.M. during 1979 which coincided quite well with the estimated flow of 2,808 I.G.P.M. During 1980, however, the flows averaged only 2,122 I.G.P.M. Flows are automatically recorded with an ultrasonic level measuring instrument and a rectangular weir plate. The 1980 recorded flows were on occasion lower than the actual flows due to some problems with the temperature compensator of the ultrasonic meter during winter months.

Total effluents leaving the Falconbridge property at the N.I.R. road average 4,403 I.G.P.M. during 1979 and 6,557 I.G.P.M. during 1980. (Figure 3) The higher flow rates during 1980 may be attributed to a 35% higher than normal rainfall which occurred mostly during the latter part of the year. The unusually high flows during August to October of 1980 was a result of the release of more water from the settling pond coupled with fall rains.

Flows are regulated at the NIR road area to minimize any flooding that may occur downstream. This is accomplished by

FIGURE 3 - FLOWS

use of two circular gate valves similar to the decant structures at the tailings ponds. Even with maximum flows of 15,000 I.G.P.M. during 1979 and 16,300 I.G.P.M. during 1980 there was no flooding downstream at Goodwill Drive. An independent report by S. A. Kirchhefer, consulting engineer and planner, indicated that Falconbridge's effluents at peak flows would contribute 2% of any flooding occurring at Goodwill Drive. (Reference #6)

2. Water Chemistry

2.1 Sulphates

Concentrations of sulpho-salts and sulphates entering the tailings area are erratic due to operational procedures and feed variability. (Figure 4) The tailings pond and polishing pond exhibit a considerable reduction in total sulphates, from the inflow. (Table 1)

Table 1

Total Sulphates - 1979 - 1980 Average

	Tailings Inflow	Tailings Pond	Polishing Pond	Effluent to Coniston Creek
Total Sulphate	1,328	790	748	601

Sulphates also continue to decrease downstream of the treatment plant. (Table 1) This may be attributed to increased dilution coupled with some precipitation of the sulphates. The effect of dilution is particularly evident during the spring thaw, April to May. Sulpho-salts are measured indirectly by subtracting sulphates before oxidation from sulphates after oxidation. When all the sulpho-salts are oxidized to sulphate, then acidification ceases.

FIGURE 4 - SULPHATE BEFORE AND AFTER OXIDATION

From Figure 4 it may be observed that the sulpho-salts decrease with distance from the inflow. This decrease is a result of the sulpho-salts becoming oxidized to sulphates during the treatment retention time of 15 weeks. The final effluent has very few sulpho-salts remaining, and are evident mainly from January to April. Overliming at the treatment plant was practiced during this period, to prevent acidification downstream.

2.2 Nickel

Nickel concentrations in the tailings pond and polishing pond have dropped by approximately half during 1980 compared with 1979. (Table 2)

Table 2 - Dissolved Nickel (ppm)

	Inflow	Tailings Pond	Polishing Pond
1979	0.7	0.7	0.9
1980	0.1	0.3	0.5

This drop in nickel concentrations during 1980 is attributed to the very low dissolved nickel concentrations entering the tailings area. (Figure 5) Several factors are believed to have contributed to this drop. One factor is the increased nickel recoveries in the Falconbridge Mill (88.07% in 1980 versus 84.37% in 1979)

Another contributing factor to the drop in nickel concentrations during 1980 is the increased lime consumption in the mill and weak acid plant.

TOTAL	985	1106	916	1027	787	308	2688	2441

* Quantities used per month during 1979 are estimated.

Finally the drop in nickel concentrations may be attributed to operational changes coupled with dilution.

(a) Increased pyrrhotite was sent to the smelter in 1980 compared with 1979 (51.4% versus 47.7% pyrrhotite in copper-nickel concentrate). Less pyrrhotite is therefore available for leaching in the tailings pond.

(b) Pyrrhotite roasting was initiated in September 1978 and ceased November 4, 1979. The pyrrhotite calcine would be expected to be leached more readily than a sulphide.

All this occurred at a time when the tailings ponds were being lowered to accommodate the spring freshet. (Figure 1) The impact due to dilution would therefore be significantly increased.

The polishing pond continues to have higher nickel concentrations than the tailings pond. (Table 2) The reason for this is unknown, however, it is believed that particulates containing nickel are entering and depositing in the polishing pond. Since the polishing pond is slightly more acidic than the tailings pond (Figure 7) then dissolution of these particles would increase the dissolved nickel content.

The treatment plant has consistently produced an effluent <1.0 ppm nickel (0.2 average). However, as mentioned in the previous report (Reference #1) and depicted in Figure 5 it may be seen that dissolved nickel increases downstream in the bog area. During high flow periods such as spring and fall, nickel is being flushed out contributing to the higher concentrations. (Figure 5) Peaks of 1.6 ppm (Spring) and

1.5 ppm (Fall) were recorded during 1980 compared with a peak of 3.3 ppm nickel during the spring of 1979. As predicted, nickel concentrations are decreasing as more of the bog area becomes neutralized and covered with vegetation.

2.3 Suspended Solids

Suspended solids leaving the treatment plant ranged from 74 ppm to 17 ppm during 1980. (Figure 6) These solids settle out in the 155 acre settling pond area such that the effluent leaving this pond meets the Ministry of the Environment guideline of 15 ppm. (5.8 ppm - 2 year average)

With an average of 44.5 ppm suspended solids entering and 5.8 ppm leaving the pond, then 38.7 ppm remain in the pond. Based on an estimated specific gravity of 64 lbs./cu. ft. for the solids and an inflow rate of 2,900 I.G.P.M., then 0.2 acre ft. of sludge per year settles in the pond. At this rate it would require 64.5 years to accummulate one inch of sludge.

Except for high flow periods (Spring freshet in 1979 and 1980) the suspended solids have met Ministry of the Environment guidelines at the N.I.R. road. The average for 1980 was 8.9 ppm.

Some suspended solids were picked up between the slag berm and the N.I.R. road. This is due to construction upstream (slag berm) and/or organics being washed out of the bog area.

FIGURE 6 - SUSPENDED SOLIDS

2.4 pH

The pH's entering the tailings area fluctuated considerably with a range of 6.8 to 12.5. A good correlation is observed with lime used in the mill and weak acid neutralization plant versus pH. (Figure 8)

In the tailings and polishing ponds the pH's exhibit a seasonal fluctuation. During May the pH's begin to drop due to increased chemical and assumed microbial activity until a stable pH of 3.5 is attained in June. (Figure 7) The pH stabilizes at 3.5 during the warm months since most of the sulpho-salts are oxidized to sulphates. As temperatures decrease fewer sulpho-salts become oxidized and higher pH's are recorded. (Figures 7 and 4)

The treatment plant effluent continued to have higher pH's than required to precipitate heavy metals. While pH's of 7 to 8 were required, pH's of 9 to 10 were discharged. This was done intentionally to neutralized organic acids in the boy area downstream. At the acid road, pH's were near neutral, except during January - February of 1980. This drop was most likely due to problems with incorrect flow measurements at the treatment plant since lower pH's were observed leaving the plant. (Figure 7)

3. Treatment Plant

3.1 Operation

The treatment plant operates on a continuous basis and is fully automated. On average the plant treats 3.6 x 10^6 I.G.P.D.

Wastewater Treatment System at
Falconbridge Ontario
Page 10A

FIGURE 7 - pH

FIGURE 8 - pH VERSUS LIME CONSUMPTION

of wastewater. Effluents have been acceptable from day one with relatively few start-up problems. Wastewater enters the plant via a 28" diameter polyethylene pipe which then reduces to a 17" diameter stainless steel line equipped with a Dezurik flow control butterfly valve. A 10% to 15% lime slurry is injected into this line which then discharges into a concrete mixing basin outside. (Flow Diagram - Figure #9) Mixing is performed by an air bubble system receiving 6 P.S.I. air from a 10 H.P. Gardner-Denver compressor in the plant. Lime is injected by a solenoid valve regulated by an automatic pH controller. The pH controller receives a signal from an ultrasonic flow recorder and pH probe to determine quantities of lime required. The temperature compensator for the ultrasonic flow meter has on occasion not worked properly during very cold weather, resulting in lower flow readings. The 1980 flow data is therefore suspected of being lower than normal during January - February.

An air dryer is located in the plant to ensure that the air activited instruments receive dry air to prevent corrosion. Since the plant has been fully automated an alarm system monitoring several critical areas has been installed. The alarm signals are located at #5 Fill Plant which is a 24 hour/day manned operation.

FIGURE 9 - TREATMENT SCHEMATIC

Table 4 - East Mine Treatment Plant - Cost Analysis

(to nearest $100.00 Canadian)

	1979	1980
Labour	$ 3,900	$ 200
Supervision	$ 11,700	$ 11,500
Lime	$ 48,100	$ 23,700
Polyelectrolyte	$ 2,200	0
Building Repairs	$ 1,000	$ 800
Equipment Repairs	$ 12,000	$ 6,800
Instrumentation Repairs	$ 23,900	$ 17,100
Supplies	$ 1,800	0
TOTAL	$104,600	$ 60,100

At a flow rate of 3.6 M.G.P.D. the 1980 costs were 4.6¢ per 1,000 gallons treated.

4. Conservation Area

The settling pond and downstream bog area became colonized with numerous aquatic plants due to the inundation of this area by alkaline water. (Reference #1) This resulted in a rapid colonization of the area by hundreds of water fowl (mostly mallards and blacks) as well as shore birds (plovers and killdeer) and songbirds (red winged blackbirds). Presence of small mammals such as muskrats, field mice, chipmunks and beaver was also

evident. Small suckers and minnows were also sighted and future surveys will indicate quantities present. In order to support the fish and bird life in this area insects must be fairly abundant. A planned benthic survey will indicate type and quantities present.

Wahnapitae River water was pumped into Red Pine Lake at a rate of 500-1000 G.P.M. in order to recharge the Falconbridge deep wells. This resulted in a dramatic improvement in Red Pine water quality such that the lake has been stocked by the Ministry of Natural Resources with speckled trout. A picnic and beach area has been added to the landscape, such that local residents now use the lake for fishing, boating and swimming.

Swamp Polishing Pond

Several hundred acres (over one square kilometer) of barren land downstream from the lime treatment plant have been restored as a result of the reduced stack emissions and through deliberate efforts of the environmental control staff.

Prior to receiving treated effluent, the pH of the denuded bog area soils were around 3.5 and the area was barren of plants, toxic and very dry.

The area was dammed off and by raising and lowering the water level for a period of 4 months, the toxic metals were rendered insoluble and therefore non-toxic as the pH was raised. Alternate raising and lowering of the water allowed more area to become inundated, treated and recolonized. The area now constitutes a very large bog covered with cattails with a wide variety of aquatic plants and algae interspersed. The bog acts as an excellent polishing area because of the high surface area of the plants which physically filter suspended solids from the water. In this way, the metal hydroxides are efficiently removed from the water treatment plant effluent.

The Biology Dept. of Laurentian University is supporting a M.Sc. thesis on the Falconbridge swamp to study the species distribution and their effect on water quality.

In some bog areas it has been observed that as the biomass dies and sinks to the bottom of the bog an anaerobic reaction takes place whereby sulfate is converted to hydrogen sulfide in minute amounts which can exert an additional polishing effect by removing metals from solution as sulfides. It would be interesting to learn whether this mechanism plays a role in Ontario bogs as expected.

The pH at the head of the bog is 9 and drops to pH 7 at the road downstream due to watershed inflow and other streams.

Dissolved nickel concentration has been found to increase downstream from the treatment plant. This has been construed as possibly due to flushing of dissolved nickel from the original contamination in the bog area soils.

Inspection of the area downstream from the settling pond in the bog revealed a considerable seepage flow from the base of the tailings and slag area into the bog. This is likely to add dissolved metals to the bog although as the seepage was coming into contact with the settling pond overflow at a high pH, a considerable degree of precipitation could be observed.

pH depression has also been construed to be possibly due to organic acids from the swamp. This is corrected for by adding excess lime to the effluent. The effluent meets M. O. E. criteria and ultimately discharges in the Wanapitei River via Coniston Creek.

Nickel is metabolized to some extent by cattails (Typha Lahfolia) in the swamp and reputedly can reach 3-4% Ni in the biomass, depending on the pH and dissolved nickel content of the surrounding water.

TAILINGS AND WASTEROCK DISPOSAL

The systems approach also has taken into account the disposal of tailings and wasterock. Sulfide rich tailings and pyrrhotite bearing tailings and wasterock will also generate acid and dissolved metals properly disposed of.

HIGH IRON-SULFIDE TAILINGS DISPOSAL

Falconbridge segregates high sulfide and low sulfide tailings and wasterock. MICHELUTTI (1978) described experiments to establish vegetation on high iron-sulfur mine tailings by appropriate use of overburden.

He concluded that the ideal overburden for high iron-sulfur tailings is a 3" layer of coarse (¼") crushed material overlain by a 3" layer of loam. The coarse material acts as a capillary barrier and prevents upward leaching of solubilized metal salts. The loam provides the growth media.

Several additional observations were made:

1. Low sulfide tailings should be pumped over the pyrrhotite stockpiles during final stages of the tailings pond to eliminate the need for overburden emplacement.

2. The use of domestic garbage, low sulfide mine wastes etc. should be investigated as overburden for the high sulfide tailings pond.

3. It was pointed out that planning between operating departments would save dollars; e.g., disposal of the open pit mine overburden materials onto tailings areas saves considerable future reclamation costs.

4. There is a need to periodically monitor vegetation to determine the effectiveness of the overburden material in achieving a maintenance free vegetation cover.

These observations were made in 1978. Since then Falconbridge has implemented all of these items and concludes that:

1) High iron-sulfide tailings and heavy metals containing materials can be segregated into a separate area of the tailings impoundment. By using coarse wasterock and domestic garbage as an overburden, such tailings can be successfully revegetated.

2) Revegetation requires a capillary barrier of some sort to prevent upward migration of acid and metals. This results in excellent vegetative growth and virtually no maintenance needs. Native species eventually encroach and restore the area to a natural environment.

Although it is now well established that covering high sulfide tailings with coarse wasterock and domestic garbage provides a way to revegetate the surface of such tailings ponds, it is still not demonstrated that acid mine drainage from such tailings will be prevented or inhibited.

M. Collins in 1975 investigated methods for inhibiting the dissolution of pyrrhotite in tailings and storage piles at Falconbridge. He concluded that pyrrhotite concentrates oxidize less readily than pyrite concentrates when stored under water. However, oxidation rates of moist pyrrhotite concentrates are increased by a factor of 10 over dry concentrates.

The Canadian Mining Association has proposed to commission a major study on all aspects of inhibiting acid mine drainage generation from high sulfide tailings such as the pyrrhotite concentrates that must be disposed of at Falconbridge and elsewhere.

Aspects of High Sulfide Tailings Disposal Regarding:

Site Hydrology

Continuity and direction of flow
Seasonal variations - flooding downstream
Flushing effects
Soil composition - effect on leachates-porosity
Groundwater slope and direction
Maximum storage capacity
Diversion of clean water

Deposition of Tailings - Method

Expected slope deposition of the material
pH of material
Acid generation - Mechanism and chemistry
Ponding
Under water deposition
Mixtures and layering
Bacterial activity
Wind Action : on water and solids
Freeze drying effects
Effect of compost and revegetation

Miscellaneous

Need for impermeable barriers
Lake or pond bottom binders
Natural regeneration of ecosystems
Surface binders
Effect of metal uptake on vegetation
Bio magnification effects

It has been found that a mixture of pyrrhotite and tailings oxidizes less rapidly than when the pyrrhotite is separated. One concept is to place the bulk of the tailings with pyrrhotite mixed and to segregate a sulfide-free slimes at the final stage to cover the tailings site, then disposing of the separated pyrrhotite under water.

SEWAGE DISPOSAL

Raw sewage from holding tanks and septic tanks are mixed directly with tailings.

SMELTER DUST DISPOSAL

Valuable matte dusts, concentrates and particles lost from the process collect in floor and yard drains which discharge into a settling pond adjacent to the smelter building. It has recently been established that the 2-3000 ton accumulation of material with 4-5% Ni has been contributing nickel via seepage to the marsh polishing pond and groundwater, but also represents metal values worth around $1.5 million. The material will be reclaimed and smelted with ore. In this way improved housekeeping will improve overall recovery of metals and avoid a former source of water contamination.

THIOSULFATE GENERATION

Ore is milled at pH 9 which is controlled by lime addition. At this high pH thiosulfates are generated. pH is adjusted during the various flotation steps and tailings leave the mill at pH 7.2. At the decant end of the tailings pond, thiosulfate oxidation has dropped the solution pH. How far the pH has dropped depends on the time of the year and the amount of thiosulfate present and the degree of oxidation. In summer, a decant solution pH of 3.0 to 4.0 is typical. In winter it is closer to pH 6.5. Thiosalts are oxidized in a large aging pond prior to lime treatment.

Weak acid from the acid plant was neutralized with lime prior to discharging to the tailings area. It has been found that lime addition was not necessary since the weak acid became neutralized once mixed with the alkaline tailings - Po, at the fill plant, prior to disposal. Operating costs were, therefore, significantly reduced.

A general layout of the mine-mill-tailings dams showing the water treatment plant, the settling pond and the marsh polishing pond is included in NORMAN & MICHELUTTI's paper.

RED PINE LAKE

Falconbridge's potable water deep wells located near Boucher Lake and Red Pine Lake had become contaminated due to years of fallout and proximity to Po disposal areas. Although acceptable in water quality, a deteriorating trend over the years was evident. This situation was resolved by taking the following actions:

(a) The deep well closest to the plants area was taken off the potable supply system and pumped to the mill for process water. This intercepted and contained most of the contaminated groundwater.

(b) 500 gpm of clean Wanapitei River water was pumped into Red Pine Lake to act as a recharge area for the other wells. Also, this clean recharge water forced the contaminated ground water away from the main potable well.

Red Pine Lake, a previously dead, contaminated lake, became exceptionally clean after recharging. This allowed speckled trout to be stocked in the lake, such that the area has become a recreational fishing, swimming area for the local residents.

DRAINAGE DIVERSION SYSTEM

A major diversion ditch system has been constructed and berms constructed where necessary to prevent precipitation from draining into the mine-mill-smelter-tailings concept.

PROJECT DEVELOPMENT AND OPERATION

Environmental improvements at Falconbridge Limited

G.E. NORMAN and R.E. MICHELUTTI
Falconbridge Limited
Sudbury, Ontario

Introduction

One of the major objectives of Falconbridge has been and continues to be, to minimize the impact of its operations on the environment around its Sudbury operations.

The approach to achieving this objective and the results, are discussed under the following topics.

1. Sulphur Dioxide Emission Improvements.
2. Effluent Treatment Improvements.
3. Effect of the Envrionmental Improvements.

Sulphur Dioxide Emission Improvements

History

The rejection of pyrrhotite in the concentrators is one method of reducing the amount of sulphur to the smelter and therefore the sulphur dioxide emissions. In the 1950s and 1960s, Falconbridge developed the capability to remove 54% of this pyrrhotite. Numerous attempts were made to increase this amount by treating the pyrrhotite for recovery of nickel and in some cases elemental sulphur. Processes tested and operated were: hydrometallurgical pilot plant, roast-leach commercial operation and nickel-iron refinery. None of these processes proved to be commerically successful for both technical and economic reasons.

Falconbridge therefore redirected its efforts to reducing sulphur emissions by improving its smelting process under The Smelter Environmental Improvement Project. A major component of this project was the installation of a sulphuric acid plant to recover the SO_2 in the roaster off-gases.

G.E. Norman

G.E. Norman graduated in 1950 from the University of Toronto in metallurgical engineering. He has worked for Algoma Ore Properties and Noranda Mines Ltd. becoming superintendent of the latter's acid plant at Cutler. After 4 years in the die-casting industry he joined Falconbridge Limited in 1968.

He was closely involved in the design, start-up and initial operation of their present smelting process and associated acid plant. Currently he is chief metallurgical engineer - projects at Falconbridge.

R.E. Michelutti

Bob Michelutti is an environmental biologist with Falconbridge Limited, Falconbridge, Ontario. He has been in the environmental control department for the past 14 years and is primarily responsible for water quality, land reclamation and disposal of hazardous wastes. Prior to joining Falconbridge, he has worked briefly with the Ontario Water Resources Commission - Great Lakes Branch. He holds a Bachelor of Arts degree in general sciences from Queen's University, majoring in biology.

Keywords: Environmental Control, Sulphur dioxide emissions, Effluent treatment, Smelting process, Sulphuric acid plant.

Acid Plant

Process and Equipment Description

The specifications for the sulphuric acid plant called for a higher order of reliability than in a standard acid plant in order to minimize its effect on smelter operations. The process and equipment for this acid plant are described in the following sections (Fig. 1).

Gas Cleaning and Cooling
Conversion of SO_2 and SO_3
Acid Production
Acid Storage and Loadout

Gas Cleaning and Cooling

A special effort was made to provide a clean gas to the converter to maximize time between cleaning and replacement of the catalyst.

The gas scrubber-cooler was designed for 98% efficiency and an outlet dust loading of 0.95 gr/Nm³. The bottom tray of this scrubber consists of Venturi tubes while the top three trays contain perforated plates. The gases from this vessel are at 40°C.

Weak acid circulating through the scrubber-cooler is cooled in both impervious graphite shell and tube exchangers and a plate type heat exchanger. These are compared in a later section. A continuous bleed-off of weak acid is neutralized in pachuca tanks using lime, slaked on site. The gypsum slurry produced is pumped to the mill tailings pond.

Six electrostatic mist precipitators are provided, 4 primary units in parallel, followed by 2 secondary units. These precipitators are built from chemical lead and designed for 11 kPa. To prevent the tubes from collapsing, polyurethane foam was blown between the tubes on the primary units while the secondary precipitators were provided with a pressure equalizing chamber around the tube section. This chamber is vented to the outlet duct from the precipitator.

INTRODUCTION

Falconbridge Limited operates several mines and a mill at Onaping, Ontario, 30 miles (48) km) N. W. of Sudbury. Copper, nickel concentrates are shipped by rail from the Onaping mining and milling complex to Falconbridge Limited's smelter at Falconbridge, Ontario, 12 miles N. E. of Sudbury.

The Onaping Complex consists of:

Mines:	Strathcona	
	Fraser	
	Onaping	
	Craig	(under development)
	Fecunis	(shut down)
	Longvack	(shut down)
	Hardy	(shut down
Mills:	Strathcona	
	Fecunis	(shut down)
	Hardy	(shut down

The Onaping operations recover a nickel-copper concentrate from ore that is also very high in pyrrhotite and low in pyrite and marcasite. Because the ore is milled at a high pH, sulphur salts (thiosulphates, polythionates) are generated. Pyrrhotite is active and oxidizes readily. The iron sulfide minerals are routed mainly to tailings impoundment areas where they generate acid and introduce some soluble nickel and other metal salts into the downstream watershed. Falconbridge Onaping operations are a good example of a systems approach to water management and environmental control.

Water management is integrated with mill tailings discharge and decantation, water recycle needs, minewater discharge and a lake system. Contaminated seepages outside of the treatment area are intercepted and pumped back for treatment. Refer to Figure 1.

The overall objective of Falconbridge's environmental control program has been to control the release of contaminants (mainly nickel) to the greater lake system outside of those lakes and ponds already affected. The second objective is to develop a tailings impoundment area that is compatible with long term restoration.

Full details of the complete system and stategy are an interesting story, but are specific to the Onaping area and circumstances, both historical, present and future. Accordingly, it is proposed to outline some of the main features and to highlight some of the more innovative aspects that may find more general application. One of the most important aspects is, of course, the overall systems approach to effluent discharge and environmental control. Sponsors are referred to Falconbridge should they be interested in more detail.

Strathcona Mill

Typical water usage rates for the present 300 dry short ton per hour production rate at Strathcona Mill are outlined below.

The source and destiny of each water stream in and out of the mill was not investigated in detail, consequently, the internal recycling of water will not be discussed in this paper. The new water intake to the mill is a blend of water from lower Moose Lake with that from Fecunis Lake.

Figure 1

Schematic Integrated Water Management System

Water Requirement at Strathcona Mill at 300 DSTPH

To Rodmill A	125 US gpm
	50 US gpm with ore
To Rodmill B	125 US gpm
	50 US gpm with ore
To Cyclone Pumpbox A	400 US gpm
Cyclone Pumpbox B	400 US gpm
Ballmill A	300 US gpm
Ballmill B	300 US gpm
Rougher Circuits	100 US gpm
No. 1 and 2 Concentrate Thickener	320 US gpm
Primary Scavenger Flotation	250 US gpm
Primary Scavenger Con Thickener	125 US gpm
Scavenger Con Regrind Mill	80 US gpm
Primary Scalp Flotation	150 US gpm
Secondary Scavenger Flotation	100 US gpm
Secondary Scavenger Con Thickener	125 US gpm
Secondary Scavenger Con Regrind Mill	50 UA gpm
Secondary Scalp Flotation	100 US gpm
Tailings Repulp Station	100 US gpm
Excess Reclaim Water to Tails	470 US gpm
Launder Sprays - floor washing	200 US gpm
Total	3,920 US gpm

Water Leaving the Strathcona Mill

H_2O contained in CuNi Concentrate shipped	70 US gpm
No. 1 and 2 Thickener Overflfow	800 US gpm
Primary Scavenger Conc. Thickener o/f	875 US gpm
Secondary Scavenger Conc. Thickener o/f	425 US gpm
Underground backfill	O to 1,000 US gpm
To Tailings pond (70 tph @ 14%)	1,750 US gpm
Total	Max. 3,920 US gpm

Net water consumption was given a 4,000 US gpm; i.e., equivalent to 3.23 tons water per ton of ore (2.9 cu.m. of water/ton ore).

The use of 2.9 cu.m. per ton ore fed to a flotation mill is relatively high and reflects the abundant availability of water at this central Ontario location.

Moose Lake Treatment System

Falconbridge has operated a concentrator at Fecunis Lake in the Onaping area of its Sudbury District operations from 1957 to 1975. Later on, Strathcona Mill began production in 1968 at a rate of approximately 2.1 million tons per year. Both mills pumped their tailings to areas which decanted into Moose Lake (see Figure 2 for geographic locations).

During the first ten year period that the Fecunis concentrator had been in operation, the water decanting from its tailings disposal area had resulted in the water of Moose Lake becoming appreciably acid (3.7). This is due to the fact that during grinding and flotation operations in the concentrator, a small amount of sulphur from the mineral pyrrhotite dissolves in the water. As a result, the chemical oxygen demand is approximately 50 parts per million. The products of oxidation called polythionates, with time, generate sulphuric acid which causes the pH of the water to decrease to levels toxic to aquatic life.

The only available solution to the acidification problem is to neutralize the acid after it has been formed. This meant the neutralization of all the decant solutions from the Fecunis tailings and Strathcona tailings areas at a location where the sulphur compounds in the solutions had become completely oxidized to sulphuric acid. Of the neutralizing agents available, limestone was the most advantageous with respect to cost and ease of handling.

Neutralization Plant

The scheme finally adopted was to wet-grind limestone chips (-1/2" +1/4") extremely fine (minus 325 mesh) dilute the wet thick slurry and introduce it into the acidic water overflowing the weir. The neutralization plant layout and equipment is shown in Figure 2 (a) and (b).

Limestone is loaded once weekly through the bucket elevator into the 50-ton bin. It is fed through the screw feeder at rates varying between 3.5 to 9 tons per day, depending on the rate of water flow in the weir, directly into the ball mill. Water, added at a rate of 1 gallon/minute serves to effect wet grinding at about 60% solids in the mill. The grinding medium consists of 275 lbs. of 2.5" diameter and 700 lbs. of 1" diameter steel balls. For the average grinding rate of 4.5 tons per day, about 15 lbs. of steel are consumed.

DILUTE LIMESTONE SLURRY ADDITION TO TURBULENT FLOW

The annual operating expense of the plant is shown below in Table 1. The ball mill is alarm-coupled to a service station located at Strathcona Mill to ensure continuous surveillance by maintenance personnel.

TABLE 1

1981 Lime Plant Costs were:

Labor	C$25,500	
Fringes	11,000	
Supplies	35,200	including limestone
Electricity	7,500	
Maintenance	17,000	
Total	C$95,000	

Results and Discussion

The lengthy retention time of the tailings water in Moose Lake allows for complete oxidation of the dissolved polythionates to sulphuric acid and the year round discharge, despite seasonal temperature fluctuations and water rates runoff, has no C. O. D. A comparison between the water quality at the tailings pond outlets during the winter and Moose Lake system outlet, before and after neutralization, is shown in Table 2.

TABLE 2

Effect of Retention Time and Neutralization
(Typical Assays)

Analysis Results ppm	Tailings Water at Tailings Dam	Moose Lake Before Neutralization	Moose Lake After Neutralization
Suspended Solids	1.5	1.0	1.0
Sulphate before oxidation	700	600	550
Sulphate after oxidation	1,000	600	550
Total Fe	6	2	0.6
Total Ni	3.0	1.2	0.8
Total Cu	0.5	0.1	0.1
pH	6.4	3.5	7.2
C. O. D.	46	less than 1	less than 1

The concentration of polythionates is determined by noting the difference in the sulphate concentration in the water before and after oxidation.

It appears that in order to ensure that neutralization will be effective, a retention period of approximately six weeks under open water and an active biological environment must be available from the time the effluents discharge from the tailings dam to the time the neutralizing limestone is added. In the spring, eight weeks are required from the time the ice has vanished to the time the biological system of the lake becomes sufficiently active to oxidize the polythionates.

Several water management and water treatment features of particular interest were observed at the Onaping operations.

1. A macro water recycling system which includes several tailings impoundments, lakes and streams has been established, thereby requiring a mimimum of water treatment facilities while gaining effective control of contaminant releases to the greater environment.

2. If a similar mine-mill complex were to be established from scratch today environmental considerations would enable advance planning so that a much smaller overall volume of water and tailings would be impacted. The Strathcona systems approach is an innovative retroactive program for a large area which had been impacted for many years before.

3. A deep natural lake was used for tailings disposal, water storage, aging and settling ponds. The lake's seasonal turnover phenomenon is taken into account as well as spring runoff effects in meeting permit effluent requirements. Some understanding and manipulation of the lake chemocline is underway.

4. Recent testwork in progress has high pyrrhotite-pyrite tailings impounded separately from low sulfide tailings, to enable sealing of the Po at a later date. Techniques are under development to use a wasterock layer as a capillary barrier in the restoration of high sulfide tailings.

5. Nickel is the most serious contaminant threat to receiving waters. It has been found that if nickel in the effluent meets the regulatory limit of 1 ppm, then everyone of the other limits is likely to be taken care of.

6. Tests are presently underway at the Fecunis tailings area to cover pyrrhotite tailings with tailings slimes to reduce nickel leaching.

7. Falconbridge employs limestone neutralization to meet the pH limits of water effluents from Moose Lake. Although limestone does not achieve pH levels required to effectively precipitate nickel, concentrations in Moose Lake do not warrant further treatment at this time. The limestone is, however, adequate to meet pH requirements and to precipitate iron.

8. By increasing the height of the neutralization dam, effluent release is now controlled at an average of 12 million US gallons per day, or 43,600 cu. m/day. Formerly, the discharge used to vary between 60 million US gpm during spring runoff and zero in summer. The uniform discharge allows better control and uniform operation of the treatment plant.

9. Falconbridge has evaluated various neutralization chemicals including limestone, quicklime, lime, cement kiln dusts, etc. Kiln dust, a cement plant waste product, was very effective in treating the water, but was uneconomical because of transportation costs.

10. Falconbridge employs coarse tailings for mine-backfill strengthened by cement. This results in alkaline minewater.

11. "Biological" removal of nickel from effluents after limestone treatment is believed to be occurring in lower Moose Lake during the summer. Nickel loading before and after treatment decreases substantially during this period, which proves that the mechanism is not dilution.

12. Metals including nickel are precipitated from water in Fraser Pond by adding tailings decant water at ph 9.

13. Control of high pyrrhotite tailings by covering with less mineralized lower sulphur content tailings over the now abandoned Fecunis tailings area will decrease the amount of nickel that leaches into Upper Moose Lake. Covering the pyrrhotite tailings will result in less oxygen reaching the pyrrhotite and therefore reduce nickel leaching and acid generation.

14. Testwork on compartmentalization of the pyrrhotite (Po) at the Strathcona tailings area is underway. The objective is to systematically dispose of the Po in the compartments and cap the Po with less mineralized tailings once the compartment is full. Local community garbage is being used to build the compartments. This will reduce the amount of nickel in water draining from the Strathcona tailings to Moose Lake.

15. The Strathcona tailings disposal integrates disposal of local garbage and sewage sludges.

Figure 3

FALCONBRIDGE ONAPING

LAKE TURNOVER MANIPULATION

Water in deep lakes located in cold winter regions "turns over" twice a year. During summer the epilimnion water (surface) increases in nickel concentration to say 1.2 ppm while the hypolimnion (deeper water) may run 0.8-0.9 ppm.

During the spring runoff, there is a considerable dilution due to the extra water flowing into the lake. Proper utilization of this cleaner water for dilution is achieved by drawing from the epilimnion or hypolimnion during different time of the year.

The deeper water can have a higher TDS level with $SO_4^{=}$ at around 600 ppm in summer while the surface may only run 3-400 ppm $SO_4^{=}$. Consequently, the denser water at th lower level beneath the chemocline may even prevent the turnover of water in late fall. Unless the lake turns over in the fall, there will remain a high nickel level in the surface water. To bring it down it may be necessary to induce the lake to turn over artificially. If this became necessary, the lake may be induced to turnover by sparging the lower depths with air.

By alternately drawing from the top of bottom (Figure 3), then the nickel concentrations may be more effectively regulated to achieve M. O. E. guidelines.

Limestone Neutralization of B-1, B-2, and B-3 Mine Waters.

BARREN WASTEROCK COVER OVER
HIGH SULFIDE TAILINGS

MUNICIPAL GARBAGE SEGREGATES POND
INTO COMPARTMENTS

TAILINGS AREAS

375 dry short tons per hour dstph of ore are milled to yield 215 dstph of tailings at 13% solids; i.e., 1600 US gpm. 55 dstph of solids end up in the tailings slimes to the pond with a composition average as follows: (for a typical day; e.g., 12-14-84)

% Ni 0.16
% Cu 0.04
% S 1.55
pH 9.0

SEGREGATION OF TAILINGS

(a) Slimes rejected from fill contain 0.1% nickel. These do not have adequate percolation rate to dewater and, therefore, won't form a proper cemented backfill.

(b) Pyrrhotite with 0.6% Ni and 23% S or more cannot be used as backfill, due to the high reactivity which will cause underground fires.

(c) Sand is also used as underground backfill after mixing with cement. There is usually not enough coarse tailings so it has to be mixed with quarried sand. About 73% of the mill tailings coarse fraction are pumped back underground as fill.

Tailings types (a) and (b) for surface disposal are kept separate. The slimes support plant growth and are a good oxygen barrier. In one case, Falcongridge Onaping has covered pyrrhotite tailings with slimes to reduce the sulphur oxidation.

STRATCONA TAILINGS

The plan is to compartmentalize the Strathcona active tailings pond using wasterock and domestic garbage. Pyrrhotite will be placed into one section while covering the rest with final tails. This will reduce the nickel amount exposed to natural leaching processes. (Figure 4)

It is planned to reduce the nickel load emanating from the active tailings pile to Moose Lake in this way.

The Strathcona tailings pond yields less soluble nickel than the smaller inactive Fecunis tailings area. This is a result of the increased oxidation taking place at Fecunis, due to the area not being utilized.

BERMS OF GARBAGE
GARBAGE COVER

Currently (1984) the ratio of pyrrhotite tailings to final tails is variable but around 2:1. The pyrrhotite settling slope is steeper (2%) than for the tailings slime (<1%). (Figure 5) Consequently, if the pyrrhotite is eventually to be covered, it may be necessary to raise the height of the dam wall which is expensive. Availablity of wasterock for all the proposed applications to make berm dams and to cover pyrrhotite may be inadequate or expensive.

Figure 5

FECUNIS TAILINGS

The inactive Fecunis tailings area was generating over 50% of the nickel loading to Moose Lake due to accelerated oxidation upon closure. The material originally deposited at this location comprised of a Po-tailings slimes mix at a 2:1 ratio respectively. To reduce acid formation and Ni leaching, it was decided to cover this area with lower sulphur nickel tailings slimes. This is being accomplished by rerouting the tailings slimes via Fraser Pond (Figure 2) to the Fecunis tailings area.

A further benefit is that the alkaline tailings slimes water (pH - 9.0) is precipitating out heavy metals. Contaminated water being displaced from Fraser Pond during this restoration measure was spilling into upper Moose Lake which was tending to raise overall Ni levels in Moose Lake. This was temporary condition, with the water quality now back to original concentrations, and steadily improving.

ANALYSIS AND MONITORING

Nickel is analyzed in a sample of Moose Lake effluent at least once a week. The discharge flow rate is gauged by measuring the flow depth in a calibrated square cross section culvert five days a week to compute a daily nickel load.

Because of the huge volume of water in the system, nickel concentration varies very little from day to day. Trends are observed seasonally and over several years.

The M. O. E. has issued a contol order to Falconbridge Limited requiring the Moose Lake Water treatment system to achieve improved effluent quality over a five year program from 1984 to 1988. Falconbridge is required to progressively reduce the total nickel loading of effluents to Moose Creek.

REVEGETATING HIGH SULFIDE TAILINGS

In abandoned impoundments containing high iron sulfide concentrations, an extremely hard cap about 1" to 3' thick forms, depending on the moisture regime. Beneath this crust, tailings, even after many years, will remain wet and unoxidized as indicated by their grey color and chemical analysis.

It has been found at Onaping that every summer, the surface of the pyrrhotite rich tailings turn from red-brown to white as soluble salts migrate to the surface by capillary action and concentrate by evaporation. The vertically migrating salts are extremely soluble, mainly iron sulphates.

If such tails are simply covered with a thin layer of clay or loam (6" to 1') and revegetated, the salts will eventually migrate to the surface of the soil by capillary action, and the plants will die. Coarse sand or gravel must, therefore, be used to stop the upward movement of water. (Ref. How to Establish Vegetation on High Iron-Sulphur Mine Tails, R. E. Michelutti, Canadian Mining Journal.)

At the north half of the Fecunis tailings site, an experiment was tried utilizing a gravel and wasterock layer over the high sulfide tailings in a layer about 4' thick. Then the town sewage sludge was pumped over the rock layer to act as an oxygen barrier to prevent oxidation of the tailings below, and also as a nutrient source.

Several plants were growing on the sewage sludge coated wasterock including many tomatoes. Some of these areas have been grassed. Ohers seem to be supporting stands of very juvenile poplar trees. This work is still experimental and not conclusive.

Very successful reclamation work has already been accomplished on the Hardy Po tailings area, and the Longvack Po tailings area. Overburden from the Hardy open pit mine was used to cover these areas at little or no cost towards reclamation. Because of the coarse overburden layer, capillary water movement has been interrupted such that the vegetation has remained very healthy with no maintenance for the past ten years.

STRATHCONA CREEK POLLUTION ABATEMENT

The Strathcona Creek watershed (Strathcona Lake, Bob's Lake and Fecunis Lake) became more acidic and contaminated with time. In 1971, Ni concentrations in Strathcona Creek averaged about 1.0 ppm while in 1984, the average concentration was 15 ppm. This was due mainly to leaching of mineralized wasterock and minor concentrate spills along the concentrate loadout track. Vast quantities of wasterock had been utilized for roads, railbeds, yards, etc. To remove the source of contamination was, therefore, not practical.

The treatment approach adopted by Falconbridge Limited was, therefore, to construct dams at Strathcona Lake, Bob's Lake and Fecunis Lake for impoundment of the contaminated water. Pumphouses at Strathcona Lake and Fecunis Lake are then used to pump the water back to Strathcona Mill. By utilizing the impoundment areas, flows may be seasonally moderated so that all of the water is contained and pumped to Strathcona Mill, negating the cost of a large pumping facility for the spring freshet.

The contaminated Strathcona Creek water is used at Strathcona Mill for process water. Since the flotation circuits require pH 9 to 11, then the water is subsequently treated. Strathcona Mill tailings water contains only 0.1 ppm dissolved nickel where it enters the tailings pond.

ADVANTAGES

1. Use of contaminated water from Fecunis Lake which contains 15 ppm Ni at pH 4 in the Strathcona Mill results in nickel removal at the high operating pH. Subsequent solution decanted from the Strathcona Mill tailings contains approximately 0.1 ppm Ni. In this sense, the mill itself is used as a water treatment plant.

2. It avoids the need for another water treatment plant.

3. It provides a backup water supply for the Strathcona Mill.

4. Lower flotation reagent consumption may result in the mill by utilizing softer Fecunis Lake water (unproven).

5. Inco Limited operates the Coleman Mine close to the Strathcona Mine and Mill. This mine also contributes to the contamination of water in Fecunis Lake. Since recycle of this water to the Strathcona Mill effectively treats this water, then Inco and Falconbridge Ltd. jointly share in the operational costs at a savings to both companies.

6. Since all of the water is contained and pumped back to Moose Lake, then only one discharge point need be closely monitored for regulatory purposes.

7. Any potential spills at the mill or minesites are now totally contained due to this system.

Waste Rock

Between 300 to 500,000 tons of waste rock are produced annually in the Onaping Area mines. The amount of waste produced at each mine varies greatly depending on the stage of mine development, the size of the mine and the ore body. Mine waste must be managed to ensure:

1. that waste production meets demand for roads, railroads, building foundations, yards, dams, etc. If demand exceeds production, projects must then be prioritized.

2. that the waste will have minimal environmental impact through its utilization or disposal.

3. that waste is utilized or disposed of in the most economical manner.

Waste is broken into two categories at Falconbridge. The first category is barren waste, or waste containing no sulfides. This material, generally found only in new mines or mines at early stages of development may be utilized anywhere. The second category is waste bearing sulfides, but at grades which are not economic to be treated. As such, it is a source of acid and heavy metals and its indiscriminate use can lead to contaminated seepage water. Therefore, the management plan requires that all sulfide bearing waste must be utilized or disposed of within the drainage basin of the Moose Lake treatment system.

After construction and reclamation requirements are met, the remaining waste must be disposed of. Disposal sites are selected for:

1. high relief to minimize its exposure to water. Alternate wet and drying of the waste in low relief areas is believed to enhance the leaching of contaminants.

2. the location must be within the drainage basin of the Moose Lake treatment system to ensure that all leachates are treated.

3. maximized depth of the disposal site to minimize the area of future reclamation.

4. minimized cost of disposal by minimizing bulldozer and haulage costs.

Reclamation with waste has several advantages on pyrrhotite tailings ponds. Direct seeding in pyrrhotite tailings is not economically feasible due to high maintenance costs. Therefore, the surface of the pond must be covered with a material suitable for grassing. The waste has several advantages, including:

1. It is readily available and close at hand.

2. Its coarseness prevents the vertical migration of toxic contaminants by capillary action.

3. It stabilizes the tailings to prevent erosion.

4. Its lower contaminant concentration vs. pyrrhotite exposes less contaminant to leaching, therefore, decreasing the contaminant load downstream.

5. It reduces the volume of water and oxygen in contact with the tailings, therefore, decreasing leaching of tailings.

6. It is the most inexpensive method of covering the tailings, and at the same time provides an inexpensive waste disposal site. Falconbridge is now experimenting with municipal sewage sludge on the waste surface. Preliminary experimentation has shown that the cost-free sewage with the waste will support plant growth and further large scale experimentation is underway on the Fecunis tailings pond.

Another approach to a leachate problem occurred in conjunction with the Onaping area potable water supply. Leachates from a waste rock railroad bed and mill concentrates leaked from rail cars and resulted in increasing nickel concentrations in nearby well water. This problem was solved with improved rail cars to prevent leaks, removing material from the surface of the track bed to the mill for processing, then adding hydrated lime to the tracks. The lime increased soil pH, and this reduced leaching by neutralizing rain, precipitating nickel and eliminated the biological leaching of the sulfide oxidizing Thiobacillus bacteria which are active only at low pH's.

Mine Water Management

Mine water quality and quantity vary with each mine, and vary with time at each mine. volumes range from 30 to 300 US gpm. Mine water pH can be as low as 6.3 in Onaping Mine which had been shut down, but cemented backfill at the other mines generally maintains pH's between 9 and 12.5. Nickel concentrations in the lower pH ranges tend to be high, occasionally reaching 16 ppm, but generally, due to this high pH, range below 1 ppm.

Onaping Mine

Due to the small volume of mine water and yard drainage generated at Onaping Mine, it is most economical to precipitate nickel from solutions utilizing NaOH. A 50% NaOH solution is fed from 45 gal. drums with a small metering pump, with NaOH consumption ranging between 15 and 45 gallons of NaOH/day. The small NaOH system is significantly cheaper than the more elaborate requirements of a lime system, and does not have the problem of limestone buildup in lines. (Note: When large water volumes must be treated, lime systems are more economical due to lower reagent cost.) The only significant problem with the 50% NaOH solution is its relatively high freezing point (53° F) making it essential to maintain the reagent warm at all times. Diluting the NaOH solution can significantly reduce freezing problems (see Figuyre 6) if heating is a problem, but will require space for tanks and larger pumps and resultant cost increases.

Freezing Points of Caustic Soda Solution

The mine water, yard drainage and NaOH discharge to a small settling pond. To increase the small pond's efficiency, an inexpensive makeshift boom and curtain was installed in the pond. (Figure 7)

Figure 7 - Onaping Mine Pond

Precipitates from this pond can periodically be dredged and processed in the mill as the sludge averages 6% nickel.

Organics such as raw sewage should be kept out of small treatment ponds. Bacterial generated gases in the organics can cause precipitates to float and result in elevated nickel concentrations in the effluent.

Long range plans could result in the elimination of the Onaping Mine water treatment system. The future Craig Mine is in planning stages. Since Craig and Onaping are to be connected underground, the Craig minewater pumping system will be designed to handle all the water from both mines. Craig and Onaping minewater will then be discharged to the existing Moose Lake water treatment system, rendering the Onaping Mine water treatment pond and pumping systems unnecessary. One pumping and treatment system will be cheaper and more effectively maintained. In addition, at Craig Mine, small clay-lined dams have been constructed to ensure that all yard drainage will drain to the Moose Lake treatment system.

Strathcona and Fraser Mines

Strathcona minewater is pumped to surface at Strathcona and pumped over a hill to the Strathcona tailings pond. Fraser minewater is pumped to surface at Fraser Mine and also drains to the Strathcona tailings pond. The Strathcona system is older and has expensive maintenance problems. Since the Strathcona Mine production is decreasing

and minewater volumes are also decreasing, it was determined that the Fraser system could handle the water volume of both mines. Since by 1986, Strathcona and Fraser Mines will be connected underground, it is proposed that all water be pumped to surface at Fraser Mine eliminating the need for the costly Strathcona pumping system, and decreasing water disposal costs.

Conclusions

1. Environmental control around a multi-mine and mill complex requires long range planning. A holistic approach rather than individualistic approaches can save money and improve operating efficiency.

2. Waste rock as well as tailings must be managed to prevent long term water contamination problems.

3. Selection of neutralization reagents depends on water volumes requiring treatment as well as the degree of treatment desired. For example, limestone was most cost effective at Moose Lake whereas NaOH was preferred at Onaping Mine.

4. Waste products such as mine waste, garbage, sewage and low grade tailings may be utilized to improve environmental problems. Control of natural processes such as bacteria and lake turnover, as well as flow rates, are useful tools in environmental control.

OPERATION GILMAN MINE

Mr. Jack Merchant (303) 328-6349

INTRODUCTION

The Gilman Mine is located on the mountainside above the Eagle River near Vail, Colorado. This zinc mine was operated since the turn of the century by The New Jersey Zinc Company and when, in the latter company's opinion, the ore deposits were exhausted, the property was sold to Mr. Glen Miller, a local entrepreneur who continued to mine a silver vein to produce direct shipping ore.

1. The Gilman Mine is interesting for several reasons. The mine is perched on the side of a very steep mountain where there was no room for a mill and concentrator. It is one of the few locations in the world where a complete mill was installed underground.

2. The underground mill was dismantled some years ago and the underground cavity was used to install a water treatment plant to adjust pH and to remove metals from acid mine drainage generated underground. Not all minewater requires treatment so a major part of the water has been segregated and discharged separately.

3. The acid mine drainage from the Gilman Mine contains relatively high levels of manganese and several interesting methods were tested to remove manganese from the effluent.

4. During 1984 the operators reputedly ran out of operating funds which presents an interesting example of the fate of worked out mines once an operation dies.

5. Gilman tailings historically were deposited on the flood plain of the Eagle River below the mine portal. This site has been declared a superfund site on account of the acid mine drainage it generates. It is reported that surface drainage from the tailings improve in quality when they flow through a cattail marsh which may be a useful location at which to study natural biological polishing phenomena.

ORE DEPOSIT & MINE

Sulfide ore deposits occurred in the dolomitic Leadville limestone formations. Mine workings dipped into the mountain at 12° and the ore was mined to formations of 30 million years of age. Sulfide chimneys extended well below the limestone formations into the underlying quartzite. The formations are underlain by Precambrian granites.

The mine portal for the Newhouse Tunnel was at the 16 level at an elevation of 8514 ft at the head of an inclined shaft. 350' below the 16 level portal at 8168 ft elevation is the 20 level sump from which there is also a portal, where both clean and contaminated acid water are collected in separate sumps and pumped to the mill level above for discharge and treatment plus discharge respectively.

The Newhouse Tunnel has been plugged and water from that level drains via three 5½" Ø holes to the mill portal level just below it where it has been treated.

Toward the portal end of the 20 level, acid metal contaminated water accumulates in a sump from where it is pumped to the underground treatment plant above before being discharged.

Further into the 20 level incline shaft is a second sump where clean water is collected and pumped separately from the mine.

Water from the Newhouse Tunnel A is collected at 16 level and piped via three 5½" Ø holes to the treatment plant in the mill cavity about 50 ft below.

Water from the 24 level has a temperature of 80° F and it was once used to preheat boiler feedwater in the plant.

Since operations have curtailed the deeper workings have been allowed to flood. There are now two pumps on the 20 level one to lift the clean water and the second to lift acid mine drainage.

TREATMENT PLANT

The AMD treatment plant is installed in the old u/g excavation for the mill. Water collected from 16 level above and AMD from 20 level AMD sump is pumped to one of three agitators, A, B and C, where lime and flocculant are added. The neutralized solution flows to a primary thickener D. Sludge from the thickener seldom exceeding 3% solids is pumped via the existing tailings line to tailings or to underground disposal.

Thickener overflow is directed to three underground chambers in series through which the primary clarifier overflow flow in series. These are old storage rooms that have been dammed up as indoor settling ponds. The untreated clean water joins the treated water stream in the second compartment of secondary settling, the commingled water is then discharged to the Eagle River.

The treatment plant was said to get good results as long as the flowrate through it does not exceed 150 gpm. Typical analyses of the treated water at F are shown in the following table. It is clear that manganese seldom meets the permit limit of 1 ppm Mn.

TAILINGS PONDS

The final tailings pond was fitted with an underdrain which has plugged up. Now the water level has risen in the ponds and discharges over the top. After heavy rains it is found that the pH of the effluent drops and the metal levels increase.

MINE CLOSURE EFFECT ON WATER QUALITY

On closing the mine water will rise in the workings thereby flooding the 20 level. Already as a result of the rising water, acid mine drainage was spilling over from the

acid mine drainage sump into the 20-10 level clean water sump. One problem expected is failure of the clean water pump because of particulates and acid in the acid mine drainage now pumped through the clean water pump which is not designed for that duty.

The first effect of rising water levels is that the underground water from the 20 level will no longer be segregated into clean and contaminated streams. This means that the full flow of water (both streams combined) will become contaminated and even if the water treatment plant were to be restarted, it does not have the capacity to treat the combined flow.

FLOCCULANT

Nalco 7871 liquid flocculant is used to aid in settling the precipitate. It is non-ionic and is added at the discharge to the lime addition reactor. Flocculant is stored underground.

LIME SYSTEM

Two lime storage tanks each hold 60 t lime pebbles. Lime solution is made up with a variable speed lime pebble feeded and a slaker. The overflow from the lime system flows by gravity to the tailings line where it raises the pH of the sludge.

DISCHARGE TO RIVER

There are two tailings ponds in the floodplain of the Eagle River below the mine. The precipitate sludge from the treatment plant is discharged to one of the ponds. Water from the mine after treatment has a pH of about 10.5. The treated water discharge flows via the wet tailings pond and decants to the river, at pH below 9 after being in contact with the tailings pond.

In May 1984 at the time RANDOL visited the property the power bill was being paid by a state agency long enough to remove transformers (containing PCBs) from the stopes before they flooded. The lime supply had reputedly been cut off because the bills had not been paid. Operators were also laid off for lack of funds to pay them.

CONCLUSIONS

1. No matter how strong a mining company may be, ownership or fortunes can change in time. Eventually a mine, even after an exceptionally long life such as at Gilman will be exhausted.

2. Gilman tailings and now the mine itself appear about to become a burden on the taxpayers.

3. For some years Gilman has experienced difficulty in removing manganese from mine drainage solutions. Manganese levels up to 31 ppm average for a month have been measured. Interesting testwork by The New Jersey Zinc Company on manganese removal using pyrolusite are described below.

COLORADO SCHOOL OF MINES RESEARCH INSTITUTE

PREDESIGN CAPITAL AND OPERATING COST ESTIMATES FOR PROCESS FOR REMOVAL OF MANGANESE FROM TAILINGS WATER

Colorado School of Mines Research Institute
Golden CO 80401

March 26, 1974

DISCUSSION

In its water discharge Permit No. CO-0000035 the United States Environmental Protection Agency stated as a condition that the manganese in the tailings water discharge should be reduced to 1 mg/liter within 12 months following issuance of the permit.

The Research Institute (CSMRI) has conducted a series of investigations of potentially applicable water treatment systems to achieve the desired reduction in manganese levels in the tailings pond effluent. Systems or approaches studied included the following:

1. Addition of freshly precipitated $Mn(OH)_2$ to tailings effluent during lime treatment in an effort to catalyze precipitation of Mn (II).

2. Precipitation of manganese carbonate rather than hydrous manganese oxide.

3. Adsorption or absorption of manganese on limestone or pyrolusite.

Experimental details and complete results of these tests are presented in the project report by D. E. Hyatt and Truman E. Louderback of October 18, 1973. With respect to the present report, it is sufficient to note that, of the procedures summarized, only the removal of Mn (II) by pyrolusite sorption was deemed practical. The other approaches failed to provide adequate Mn (II) removal or required clearly excessive reagent consumption and cost.

Based on the preliminary indications of success in using pyrolusite to remove Mn (II) from the tailings effluent, additional studies were conducted in early 1974 to ascertain likely scale-up factors in adapting laboratory findings to field conditions. Investigations, using actual tailings effluent and

Mr. A. S. Winters
Manager
The New Jersey Zinc Company
Gilman, Colorado 81634

Dear Mr. Winters:

The purpose of this letter is to report on the test work to determine the adsorption rate of Manganese II from your tailings effluent water on Gilman pyrolusite. Also a preliminary sizing is given of an adsorption system for lowering the manganese in 1000 gpm of water from 5 mg/liter to 1 mg/liter.

SUMMARY

1. Gilman pyrolusite again demonstrated an adsorptive capacity for MnII from plant tailings water.

2. Based on the test work conducted, a preliminary design indicates the need for two 12 ft diameter tanks in series, the first containing a 5 ft depth of $\frac{1}{2}$ in. x $\frac{1}{4}$ in. Gilman pyrolusite and a second containing a 5 ft depth of $\frac{1}{4}$ in. x 10 mesh Gilman pyrolusite. A supplementary tank for mixing regenerating solution should also be provided as well as a pump to elevate spent regenerative solution to the surface of the tailings dam.

DISCUSSION

Water Sample

A 55-gallon sample of clear effluent was collected from the Gilman, Colorado operation of the New Jersey Zinc Co. on February 22, 1973. The sample container was plastic lined. The water at the time of sampling had a pH of 10.4 and a temperature of 2°C. The manganese content of the water which was determined upon return to Golden was 0.05 mg/liter.

Pyrolusite

A 100-lb sample of pyrolusite was obtained from the New Jersey Zinc Co. from a bin on the mining property.

This mineral, which is native to the mining area, was reportedly extracted and stored in this bin in the 1940s. The particles in the sample ranged in size from about 3 in. down to fines. The sample was split in half and one-half retained for possible future use. The other half was crushed to minus ½ in. size and separated into ½ in. x ¼ in. size and minus ¼ in. size. The specific gravity of this sample of pyrolusite was determined to be 3.3.

Adsorption Tests

Unfortunately the pH of the sample was adnormally high and the sample contained little or no manganese in solution. Adjustment would have been necessary in any case to develop the relationships necessary for the preliminary design.

Two solutions were prepared from the tailings effluent for adsorption tests. Reagent grade $MnSO_4$ was added to one solution to obtain approximately a 5 mg/liter concentration of manganese and the other solution to obtain a concentration of 2.5 mg/liter. The pH of each solution was then adjusted to a pH of 7.8 by addition of sulfuric acid. The analysis of the solutions for Mn content after preparation was as follows:

Solution 1 -- 5.0 mg/l of Mn
Solution 2 -- 2.55 mg/l of Mn

Two adsorption columns were prepared using ½ in. x ¼ in. pyrolusite in 250 ml burets and 359 grams of the pyrolusite were required to fill the burets. The void volume in these burets after pyrolusite addition was determined at approximately 46%. In the various tests, the prepared solutions were percolated upwards through these columns, and in each test after the percolation of several void volumes, a sample was taken and analyzed for manganese content. The results of these tests are summarized in the following table.

Feed Solution 5 mg/liter Mn			Feed Solution 2.55/liter Mn		
Percolation Rate, ml min	Solution Retention Time, min	Effluent mg/liter Mn	Percolation Rate, ml min	Solution Retention Time, min	Effluent mg/liter Mn
7.2	20.0	0.6	7.8	17.8	0.62
10(1)	14.4	0.8	20.0	7.0	0.80
15.0	9.6	1.4	25.3	5.5	1.53
20.0	7.2	1.5	46.0	3.0	1.72
38.7(1)	3.7	2.2			
70.0	2.0	2.8			

1/ pH adjusted to 8.8 before percolation

These results permit the following observations:

1. The efficacy of Gilman pyrolusite for adsorption of Mn II from the tailings water was again demonstrated.

2. The adsorption rate was shown to be a function of the manganese content of the feed solution and the retention time in the column.

3. pH apparently did not influence the adsorption rate between the ranges tested (7.8 to 8.8).

These results are expressed graphically in Figure 1 with adsorption rate as mg of manganese per minute per square meter of the surface of the pyrolusite plotted against percent removal from the feed solution. As can be seen, as the percentage of removal increases, the amount removed per unit of surface area in a given time decreases.

The adsorption system using pyrolusite for removal of soluble MnII is, according to the literature, self-regenerative to a degree. MnII is adsorbed and in time oxidized to $MnO_{1.3}$ to $MnO_{1.9}$ which is an adsorbent for incoming MnII in solution. In time, however, the size of the particles in the column increase due to adsorbed manganese and other metals and the flow of the solution becomes restricted. In this event, the column must be treated to restore permeability. One method that

has been used i the soaking of the column in a 10% solution of caustic for several hours followed by a water wash. The washings in this situation could be returned to the surface of the tailings dam.

The pyrolusite must be crushed to prepare adsorption columns or tanks in order to prepare a size that has a considerable surface area compatible with a reasonable downward percolation rate. For purposes of preliminary design, we have considered crushing to minus $\frac{1}{2}$-in. size and preparing three sizes as follows:

1. $\frac{1}{2}$ in. x $\frac{1}{4}$ in. for the first column
2. $\frac{1}{4}$ in. x 10 mesh for a second column
3. Minus 10 mesh for addition to the surface of the plain upstream from the existing measuring weir.

A preliminary study has been conducted considering the design of the first column for removal of 50% of a 5 mg/liter concentration from a flow of 1000 gallons per minute and a second column to remove 60% of the manganese remaining.

The first column would thus remove 2.5 mg/liter and the second column 1.5 mg/liter. The first column where the maximum amount of manganese would be removed would be packed with $\frac{1}{2}$ in. x $\frac{1}{4}$ in. pyrolusite and the second column with $\frac{1}{4}$ in. x 10 mesh pyrolusite. Using this approach, the column with the smallest voids would be removing the lesser amount of manganese and this would extend the time before regeneration was necessary. Moreover, the second column would treat a weaker solution which has a lower adsorption rate per unit of surface area. This column, however, with finer particles would have a higher surface area per unit weight of pyrolusite.

A ton of pyrolusite at $\frac{1}{2}$ in. x $\frac{1}{4}$ in. size at a specific gravity of 3.3 was computed to have approximately 165 square meters of surface area and a ton of $\frac{1}{4}$ in. x 10 mesh pyrolusite, 393 square meters of surface area.

A flow rate of 1000 gallons per minute at 5 mg/liter of manganese would be equivalent to 18, 925 mg/min and at a 50% removal according to Figure 1 at this concentration, an adsorption rate of 1.75 mg/minute/square meter of pyrolusite surface.

$$\frac{18,925 \times 0.5}{1.75} = 5407 \text{ square meters of surface area required}$$

$$\frac{5407}{165} = 32.8 \text{ tons of } \tfrac{1}{4} \text{ in. x } \tfrac{1}{4} \text{ in. pyrolusite}$$

The second column at 60% removal from a 2.5 mg/liter solution and an adsorption rate of 0.45 mg/minute/square foot of surface area would be:

$$\frac{9463 \times 0.6}{0.45} = 12,616 \text{ square meters of surface area required}$$

$$\frac{22,616}{393} = 32 \text{ tons of } \tfrac{1}{4} \text{ in. x 10 mesh pyrolusite}$$

Assuming the weight of the struck volume of the pyrolusite at 120 lbs per cubic foot, and a bed volume of 5 ft depth, the contact columns or tanks should consist of two - 12 ft diameter tanks. These tanks could be constructed of either steel or wood staves. They should be fitted with a false bottom to retain the pyrolusite and a system to distribute the feed solution fairly equally over the surface of the pyroluste.

A sand filter system which is generally 4 ft deep and composed of both gravel and sand has a percolation rate of between 2 to 3 gallons per minute per square foot. This system would be required to have a percolation rate of 8.85 gallons per minute per square foot which would seem conservative for a gravel system without sand. It is recommended that about 12 ft by 12 ft tanks be used allowing 1 ft for the false bottom, 5 ft for pyrolusite and 6 ft of freeboard. More and more freeboard will be required as the size of the particles increase during adsorption. The need for regeneration would be determined when the tank is near overflowing with water.

A supplementary tank should be provided for mixing solution for regeneration or cleaning the pyrolusite. Moreover, a pump should be provided for elevating the solution from regeneration to the surface of the tailings dam.

This proposed design for the manganese adsorption system is preliminary. I am sure we will wish to discuss the amount of pyrolusite available, how it may be crushed and sized, tanks for the columns that might be available of a different size, etc. We will look forward to your comments.

Yours sincerely,

F. T. Davis, Director
Environmental Technology Division

INTRODUCTION

INCO, the company around which Sudbury has grown into a small city, operates 11 mines and three concentrators within Ontario. The Copper Cliff facility covers an extensive area - perhaps 25 square miles. In addition to the mines and mills, it includes the Copper Cliff flotation plant which separates bulk concentrates into copper, nickel and pyrrhotite concentrate and tailings, fluid bed roasters, a large acid plant, a copper and a nickel smelter and copper and nickel refineries.

This brief summary does not go into much detail on the metallurgical operations, but it is possible to highlight some of the principles on which INCO's water management and treatment program is based. Managing water and controlling the environment around such a huge and complicated mining and metallurgical complex is no mean feat.

Aspects of particular interest are:

1. The macro management of Water & Recycling.

2. The Copper Cliff Water treatment plant.

3. Tailings Disposal and Site revegetation program.

4. Reference to an improved arsenic removal process.

5. Recycling of water containing thiosalts.

LOCATION

In the outskirts of the City of Sudbury, Ontario.

CLIMATE

Continental with 8" net rainfall over precipitation and a long frozen winter.

TOPOGRAPHY

Rolling hills with rock outcrops and with numerous lakes and creeks flowing through the area.

PRODUCTION

The Copper Cliff plant has a nickel production capacity of 220,000,000 lbs per year (100,000 mtpy). Production capacity has been pared back considerably due to present environmental protection constraints particularly with respect to SO_2 emissions. But for these restrictions, capacity would be around 375 million lbs nickel/year.

THE INCO PROCESS

Ore from 11 copper-nickel mines is milled at three plants and a bulk concentrate delivered mainly by pipeline to the Copper Cliff plant for separation. The operations flowsheet is depicted above and gives some idea of the complexity of the total operation.

The Copper Cliff mill receives around 12,000 tpd of bulk copper-nickel-pyrrhotite concentrate from the satellite mills. Copper Cliff tailings (two types) are pumped together with Clarabelle and Frood-Stobie mill tailings to two sand plants and a disposal area.

The general arrangement of mills and smelter is depicted schematically below as shown in "Milling Practice in Canada (1978)" and the general arrangement of the Copper-Cliff-Clarabelle circuit is shown also.

Water requirements, management and effluent disposal around such a multi-faceted mine-mill-smelter-refinery-tailings-wasterock-townsite is complex, especially at first sight. For the casual visitor, just grasping the general arrangement of the various components of the operation even with the help of an excellent model of the area, is difficult at first.

Flotation of the bulk Cu-Ni-Pyrrhotite concentrate is carried out at pH 6.5-7.5 using K-amyl xanthate as collector.

The separation flotation is carried out at pH 11.0 and above in heated pulp with cyanide and $CuSO_4$ addition using a reagent K-amyl xanthate which under these conditions is very selective for copper sulfides.

Roaster gases from the Nichols-Herrschoff multi-hearth furnaces yield a roaster gas with only 2% SO_2 which is too low to make sulfuric acid. Pyrrhotite is roasted in fluid bed roasters and yields 12% SO_2 in the offgas which is diluted to 8% at the converter for optimum results.

INCO at one time released 6-7000 stpd SO_2 to the atmosphere. This has been reduced to 2200 stpd SO_2 under present conditions with further pending measures to reduce the SO_2 levels still further.

In order to control the metal contact of aqueous effluents it is important to look at gaseous emissions and aqueous emission control as one integrated problem.

MACRO MANAGEMENT OF WATER & RECYCLING

The Ontario Division of INCO Ltd. uses 89.1% recycled water, although no detailed water balance has been developed.

Net new water consumption by INCO's Ontario Division is as follows:

Plants	53,418 m^3/d
Townsites	59,072 m^3/d
Mines	18,479 m^3/d

Reclaimed water use amounted to the following:

Mill Water Recycling	98,795 m^3/d
Smelters	26,473 m^3/d
Mines	48,000 m^3/d

Total volume of water recirculated in the operations amounts to 636,678 m3/d, which includes all internal water recycle loops. At Copper Cliff all yard drainage water is collected and treated in the Copper Cliff Treatment Plant.

WATER SOURCES

Water is drawn from two rivers and one lake in the region.

Water supply in most of Ontario which has a net positive precipitation and numerous lakes and rivers is seldom a problem. Consequently, considering the large number of potential water supply sources in the vicinity of the complex, this aspect did not deserve attention. A considerable amount of water is collected from surface drainage and used with recycled process water. The INCO tailings dam system also includes a very large water impoundment to smooth fluctuations in supply. The cost of fresh water to INCO is C$0.70/1000 Igal or US$0.21/m^3.

Fresh water is drawn from the Vermilion river 7 miles from the site and pumped to a central potable water supply reservoir with 16,000,000 I gallon (73,000 m^3) capacity. Potable water is treated by prechlorination, sediment settling, filtration, postchlorination, fluoridation and distribution.

The main principle employed in water management at INCO's operations is to bring all tailings, slimes and decant water to the central tailings pond for aging before discharge via a treatment plant or recirculation. The central tailings pond had a 2 billion gallon (9 million m^3) inventory of recycled water. At one point residence time of water in the central tailings pond was measured to be only two hours which indicated an amazing degree of short circuiting. This is one more example of a case where shear size of an impoundment does not mean an equivalent residence time. The most significant recycle loop is from Copper Cliff Creek upstream of the effluent treatment plant where water is collected from a weir and pumped to the upper pond reservoir. 20 million Igpd (90,000 m^3/d) of water is recycled in this main loop.

COPPER CLIFF WATER TREATMENT PLANT

Water decanted from tailings and surface runoff collects in the Copper Cliff Creek flowing Southeast. As much water as is required is pumped from the creek to the upper pond reservoir. Immediately after the pumphouse, treatment of the balance begins with addition of slaked lime slurry directly to the creek upstream of the treatment plant.

An average of 60 million I gallons/day is treated, i.e., 272,000 m^3/d. Total treatment costs are C$0.30/1000 I gallons (US$0.06/m^3) or C$18,000 per day.

The Copper Cliff water treatment plant was installed in 1975 at a cost of C$4.1 million.

The water treatment plant consists of a two compartment raw water well into which the Copper Cliff Creek flows at around pH 10-10.5 which is at or close to the theoretical minimum solubility of nickel according to JENKINS, et al. (1964). The two compartments are separated by a trash screen which prevents trash, including vegetation matter such as cattail leaves, etc., from getting into the pumps. Three vertical shaft pumps each with 15,000 gpm (100,000 m^3/d) capacity are installed in the second raw water well to pump the water to two EIMCO 135'Ø reactor clarifiers, with 22' sidewalls and 2.5 mm US gallon capacity, installed in parallel.

Alchem 8C26 polyelectrolyte liquid polymer delivered at 0.5-1.0% concentration is diluted 10:1 and dosed at 0.6-1.5 ppm via metering pumps to the feedline to the two reactor clarifiers. The polymer works best around pH 10.0.

AVR blowers are installed to aerate the surface of the clarifier water in winter as a de-icing measure.

Clarifier overflow is collected in submerged (3') radial launders which allow the outdoor clarifiers to function even when covered by a layer of ice in winter. The reactor clarifier is operated with a sludge blanket.

Underflow sludge density is around 2% and is discarded with tailings to the tailings area, being mixed at the tailings pump sump. Each sludge pump has a capacity of 450 gpm (120 m^3/h). The sludge runs 3.4% Ni and 0.2% Cu with iron hydroxide as the main constituent.

Normally sewage is added to the underflow sludge ahead of being pumped to the tailings pond, except during winter when it is added to the effluent stream in the first stage of the raw water well.

The Copper Cliff water treatment plant uses quicklime for pH adjustment. The lime is supplied from a source in Michigan. Total quicklime purchases for environmental uses at INCO Ltd. is 4000-5000 tpa.

Operating at pH 9.5-10.5 for metal precipitation means that nickel close to its minimum solubility, and at this pH, copper and iron are also effectively removed.

INCO has found that moving the addition of lime to the stream a distance ahead of the clarifier system has resulted in a significant improvement in the reactor-clarifier performance and in the quality of the final effluent.

PIPES

INCO Ltd. has used Woodstave lines with success but recently all new pipe being installed is high density polyethylene.

TAILINGS DISPOSAL & SITE REVEGETATION PROGRAM

The INCO complex includes very large tailings disposal areas in various stages of development, activity or restoration. In 1984 a 2500-acre new tailings area was being developed which will store 48 million tons of pyrrhotite of the overall 400 million tailings to be disposed of. The new area will cover Meatbird Lake and surrounding land. A map of the area reveals several above-ground tailings ponds:

'M' Tailings Area - Active
'M' Tailings Area - Abandoned
'C' & 'D' Tailings Area - Abandoned
'Q' Tailings Area
'P' Tailings Area

The overall tailings area measures 15,000 ft by 18,000 ft and it takes advantage as much as possible of a natural depression in the topography to the west of Copper Cliff.

Tailings are pumped to a sand plant at Creighton Mine where the sand is used as backfill. Slimes and the cyclone overflow are pumped back to the tailings area. Minewater removed from the underground mines is pumped back to the tailings pond with the slimes fraction.

At South Mine and the Clarabelle Mill, all tailings are cycloned, to separate sand for backfill, and slimes are pumped to the tailings pond. The underground minewater sump from South Mine is pumped direct to the tailings pond.

All effluent and sewage from the Nickel Refinery Complex and Iron plants are pumped to the tailings area where they are decanted.

No linings or geotextiles are used in the tailings pond construction. The tailings dams are constructed one at a time in sections which when full can be reclaimed and vegetated. In 1971 the decision was made to construct a very large tailings dam with the objective of establishing a substantial body of water which would be useful in smoothing out the water balance.

INCO has developed a technique for revegetation of their tailings areas. Lime and fertilizer is disced into the surface of the tailings which are then seeded. Tom Peters at INCO, Sudbury, is in charge of the agricultural division which has been experimenting in several innovative ways of using mine tailings and underground stopes for agricultural purposes.

When tailings are placed on the pond the surface is stabilized to minimize dusting problems. The cost of chemical stabilization of tailings solids runs around C$750,000 per year, of which C$250,000 is for the chemical itself.

A product known as HERCOBOND from Hercules Chemical Co. is used at INCO for tailings stabilization. It is one product of several used by the INCO Agricultural group and costs C$0.65-0.70/Kg. The Hercobond is applied using a track vehicle which exerts 3-5 psi to pull a hydroseeder. Several other products have been tested including Curasol (an oil derative), Coherex (used by Climax Molydenum Division, Utah International Copper Division, and Kennecott at Bingham Canyon).

TAILINGS DECANT SOLUTION SIPHON SYSTEM

The largest INCO tailings dam at Copper Cliff was equipped with a 120 ft decant tower which fed an underground tunnel to recover excess water from the pond to Copper Cliff. Around 1982 windblown iceflows caused the decant tower to break off at the base at the point where it was joined to the mouth of the tunnel. This resulted in the draining of the tailings pond to Copper Cliff Creek with considerable silting problems in the creekbed and water treatment plant as well as minor flood damage.

The tunnel opening was sealed by dropping a concrete plug into it. The decant tower has been replaced by a 3,200 ft long siphon with a 80 ft vertical drop from the tailings pond level to the Copper Cliff Creek.

A total of 66,000 USgpm peak flow must be accommodated in the design. This is provided via two parallel steel pipes each with 33,000 USgpm maximum capacity. Normal operation will be at 22,000 USgpm.

Vacuum is provided by two NASH CL202 vacuum pumps capable of evacuating both lines to 22" mercury in two hours. The system can be operated so that one pipe is connected to the vacuum pump in a compressor mode allowing it to blow out the water from the static line to prevent freezing in winter.

Because the lines are buried well above the phreatic surface of the tailings dam wall, this wall would not be in any danger of failure even if there was to be a pipeline failure.

The lines were laid across the tailings surface over a bed of geotextile and crushed rock which serve as foundation for the pipeline.

The steel pipelines consist of 42"Ø 0.404" steel wall lines with 24"Ø 0.375" wall pipes for the last 400 ft. The purpose of the smaller diameter tail section is to put less pressure on the discharge valve.

Problems with frazzle ice formation at the outlet which caused problems at the water treatment plant downstream on Copper Cliff Creek were solved by installing tailpipe extensions right down to the Copper Cliff Creek water level. Severe vibration of the tailpipes occurred until the problem was solved by drilling holes to allow air to enter at the junction of the tailpipe sections to the end of the siphon.

Behrent Engineers of Toronto acted as consultants in the evaluation of the siphon system. Major advantage of the siphon system are:

- It is safe
- It can be readily automated
- Flow can be inercepted by breaking the vacuum.
- It is less espensive than the system it replaced.

Other siphon water transfer systems have been installed in North America at Kennecott Minerals Company's Bingham Canyon operation (2 @ 24"Ø) by Ontario Hydro at Orillia, Ontario for a hydro electric scheme (72"Ø) and ERCO in Newfoundland (34"Ø).

COPPER REFINERY 'BOSCHWATER' TREATMENT: ARSENIC REMOVAL

In the copper refinery, anode cooling water is recycled to a separate pond using surface aerators to cool the water. Overflow from the pond is discharged to Copper Cliff Creek.

Effluent from the Copper refinery which contains arsenic is discharged to the tailings pond. Addition of excess calcium to this stream precipitates the arsenic as Ca Fe Arsenate which is found by INCO to be insoluble at relatively low pH - even lower than rainwater, i.e., pH 5-6.

No details were provided on the performance or nature of the arsenic removal process and further engineers were referred to:

RECYCLING OF WATER CONTAINING THIOSALTS

Copper-Nickel-Pyrrhotite bulk concentrates are delivered to the Copper Cliff flotation plant where the various concentrates are separated at a high pH. Some evidence is found of thiosalt generation, and there is some sign of pH depression in Lake Kelley into which the Copper Cliff Creek flows with Copper Cliff effluents.

Thiosalts and thiosulfate are generated from sulfide ores particularly those that contain pyrrhotite when they are milled at a high pH.

At INCO's Longvack mill there was a pH drop due to thiosulfate oxidation. The Longvack Mill was shut down due to poor economics.

According to INCO, the worst impact of thiosulfate on an aqueous environment is the lowering of pH as below pH 5.5 fish egg hatching is adversely affected.

The direction of all tailings to a large central tailings pond with around 2 billion gallon capacity. One purpose of this is to allow the water to age whereby thiosulfate can be oxidized. However, tests have shown that actual residence time in the pond is surprisingly short due to short circuiting.

Thiosalt levels have been found to be very high in some internal circuits which contain effluents generated by wet scrubbing of exhaust gases from the furnace. The thickener overflow after dewatering the Cu Ni dust slurry from the wet electrostatic precipitators is high in thiosalts and as a result this solution had to be redirected to a different part of the circuit. It used to be used in the flotation plant.

INCO

The Nickel concentrate filtrate now ends up with the thickener overflow and is directed to the upper pond where it is mixed into a very large volume of water and then returned to the mill process in diluted form. Flash furnace water contributes a mere 200 gpm to the 13,000-14,000 gpm Upper Pond water recycle flowrate.

Due to thiosalt and thiosulfate levels there is virtually no oxygen in the recirculating millwaters used at INCO's Copper Cliff operation. It is important to aerate all pulps in flotation circuits to replenish oxygen levels for the flotation process to work well.

SEWAGE

The Copper Cliff complex employs a large sewage treatment facility. Sewage reclaim water is segregated. 250,000 - 1,000,000 lgpd sewage reclaim water is generated (ave. 23 mm lgpm) which is equivalent to an average of 480 m^3/d. Reclaimed sewage water is used as process water in the smelter as well as for mill glandwater and firehydrants. Sewage sludges are disposed of with the water treatment plant thickener underflow which are pumped to the tailings pond. The Copper Cliff sewage plant includes an activated sludge digestor to remove BOD. Sewage reclaim water is used in the venturi scrubbers for dust collection and cooling of SO_2 containing gases as a means of scrubbing SO_2.

EFFLUENT DISCHARGE

The Copper Cliff plant discharges 86,000 - 160,000 m^3/d treated water. The Copper Cliff Creek eventually drains via Lake Kelley to Lake McCharles which supports sportfishing. The effluent treatment plant may contribute up to 50% to the flow of Copper Cliff Creek.

HYDRAULIC FLUIDS IN PROCESS WATER

Mine-Mill-Smelters-Refineries-Tailings complexes using an integrated water system require that a systems approach be adopted. Factors at one end of the process, say in one of the mines, could end up causing a beneficial or a deleterious effect at another end - say in the flotation recovery efficiency.

A routine survey of various consumables turned up the fact that 900,000 gallons per year of oil were being consumed underground. This was tracked down to frequent breakage of hydraulic hoses on scoop trams underground which were using oil as hydraulic fluid. It was found that the temperature rating of the hydraulic hoses was inadequate but has been rectified.

The advantage of using engine oil as a hydraulic fluid in underground mines is that only one oil container need to be transported underground.

The oil lost underground reported with the ore and minewater and was suspected of interfering with the flotation process. Now each mine has waste oil tanks and oil is recycled.

CONCLUSIONS

1. Even on such a large complicated mining and mineral processing complex as INCO Ltd's operations at Copper Cliff, it is possible to simplify the overall water management plan. Recycling of water on a macro scale results in no noticeable deterioration in flotation recoveries.

2. Even a simple water treatment process - addition of lime to an effluent ditch and settling in reactor clarifiers, results in an effluent that has been found acceptable to regulatory authorities.

3. Numerous innovations have taken care of ad hoc problems such as disposal of sewage, oil disposal in mines, thiosulfate generation in gas scrubber circuits, etc.

   An interesting sideline of the same survey that identified the hydraulic oil problem was a survey of pH of the 28 varieties of soap used on the INCO complex. The pH's ranged from pH 7.5 to 12.0. The high pH soaps caused a high incidence of dermotitis which was a factor in absenteeism until corrected.

4. INCO is not interested in the incorporation of biological polishing marshes to treat their final effluent - Cattails break loose and have been found to become a significant nuisance in water courses especially where the water is to be recycled.

INTRODUCTION

The Kidd Creek copper-lead-zinc-silver-tin complex is one of the richest ever discovered. The Kidd Creek orebody is separated in two distinct zones, a North orebody and a South orebody. Two main ore types occur within the North Orebody - a siliceous copper ore containing stringers of chalcopyrite in a cherty breccia with occurrences of massive chalcopyrite, and a massive sphalerite-pyrite ore containing native silver and galena. The South orebody is characterized by a mixed ore containing massive chalcopyrite and sphalerite with lower silver, pyrite and galena concentrations.

From 1965 to 1977 when the 800 ft. deep open pit mine phased out 50,000,000 tons of wasterock, some containing sulfides, accumulated on the surface around the minesite. Since 1977 production has been from underground mine operations which today yield 19,000 tons per day of ore 5 days per week which is transported by company rail line to the metallurgical facility about 17 kilometers to the southeast. There are two mineshafts, No. 1 to 3000 ft and No. 2 to 5000 ft.

CLIMATE

The mine is located close to 49° north latitude in a continental climate region. Up to 120 inches of snow can fall annually. Net precipitation is typically 17" but varies significantly year to year. For example 1982 was such a dry year that the potable water supply was threatened. 1984 was a year of record rainfall.

During 1984 with its exceptionally high rainfall and runoff volumes, it has been difficult to achieve the 1 ppm THM target at the treated effluent discharge point.

GRADE CONTROL

The Kidd Creek orebody is zoned and is variable. Parts of the orebody can range up to 60% chalcopyrite. The concentrator can handle feed with up to 3% chalcopyrite, 4% lead, and 5% zinc. Consequently ore must be blended before it is shipped to the mill. 1984 budgeted ore quality is:

Pb	0.9%
Zn	7.0%
Ag	202g Ag/t
Chalcopyrite	3%

Ore is crushed to minus 6" underground and stockpiled in various piles for blending to meet the above grade.

WATER TREATMENT PROGRAM

Drainage from the wasterock as well as the ore stockpile areas, yards, open pit and underground workings covering 2,200 acres is collected to a treatment pond system.

Lime is added and thoroughly mixed with this water as it passes through two corrugated culverts.

pH of the water is raised to above pH 10.5 to precipitate heavy metals. Water pumped from the mine varies from 500 gpm to 1600 gpm depending on the time of year. (2700-8700 m^3/d).

Total average flow through the treatment ponds, including surface drainage to the treatment ponds, is approximately 3,000 gpm (16,000 m^3/d).

Lime consumption is approximately 1100-1400 short tons per year to keep heavy metals below compliance levels (0.3 ppm Zn max). The rate of automated lime addition is adjusted manually based on metal content and flow of the incoming water. Past investigations have shown that heavy metals in the effluent are at a minimum when the pH is controlled at pH 10. The lime plant shuts down for the winter from October of each year when the tailings pond decant freezes.

The following diagram shows the layout of the mine complex in relationship to the creek and the water treatment reservoir. Typical analyses of the water supply, treated effluents, recycle water and receiving waters at the minesite are provided below.

All water from the site ultimately drains via the Kidd Creek to the Mattagami River.

Underground minewater has a temperature of around 45°F right through the year.

Water pumped from the mine including water used for mining operations averages approximately 1000 gallons per minute. Minewater is slightly alkaline and is very low in heavy metals - (normally well below levels in natural creek waters), but the water from surface stockpiles contains elevated levels of metals. Even the runoff water metal levels are normally below the concentrations accepted as TLV's for a public drinking water supply in Canada (5 ppm Zn), but of course way in excess of levels considered to be harmful to aquatic ecologies.

Oxidation of sulfide minerals is enhanced at temperatures above 10°C, and accelerates as the temperature rises. Dissolved metals then are flushed out during periods of precipitation and when a heavy runoff of surface water occurs.

POTABLE WATER

100 gpm of water is pumped 4 miles from Feldman Lake (which is spring fed as well as receiving surface drainage) and rendered potable in a chlorination plant for use in service shops, offices, surface change and washrooms, underground lunchrooms, drinking fountains, and toilets.

Treated potable water is delivered to the mine by a separate small line in the shafts to lunch and washrooms on all main levels. Potable water and service water are kept separate.

The mine workforce numbers 900. Potable water use is allocated as follows:

Workshops	30%
Fireline	14%
Backfill Batch Plant	4%
Compressor Cooling	4%
#1 shaft underground drinking water	12%
#2 shaft underground drinking water	2%
Administration Building (incl. showers)	34%
	100%

About 600 gpm (3300 m^3/d) of treated water is recycled from the creek for use in mining and drilling equipment, water sprays for dust abatement, washing down roadways and other miscellaneous underground requirements.

SEWAGE TREATMENT

Waste water from surface washrooms located near the two mine shafts is treated in a sewage lagoon. The treated effluent drains into the treatment ponds.

Wastewater from washrooms in the maintenance shops and warehouse areas is treated in a large septic tank and disposed of through a large tile bed.

Wastewater from underground washrooms on each main level is treated in small septic tanks. The septic tanks are emptied periodically and the material disposed of in the surface sewage lagoons.

TREATMENT PONDS

The treatment ponds were constructed in the bottom of a natural creek bed. A bypass ditch was excavated to carry the creek water and the treated effluent around the treatment ponds and back to the original creek bed. There are three distinct ponds interconnected with decant towers so that the water level can be controlled in each section. Provision for emergency overflow is provided in case there is a flash flood - e.g. spring runoff or from rainfall in excess of 2 inches in 24 hours.

LIME PRECIPITATE MANAGEMENT

Metal hydroxide precipitates that settle in the pond are removed as a consolidated sludge by dragline from the first pond once a year. The material is stable and high in lime and is piled at the sides of the pond.

TREATED WATER RECYCLE

A pump station capable of returning up to 1000 gpm (5500 m^3/d) through a 6" insulated surface pipeline is installed adjacent to the outlet culvert of the last decant tower. This pumping station was located to draw water from a basin that would receive most of the creek water plus treated effluent. The water level in this pond is maintained within a narrow range by constructing stone dams or weirs in the creek bed and bypass ditch. Recycled water is delivered to the main water lines in the shafts, for distribution to the different levels and all the working areas of the mine.

PEATMOSS EXPERIMENT

Kidd Creek Mines Ltd. propose to experiment with the use of peatmoss as a passive water treatment step to remove metals ahead of lime precipitation. The motivation is to use less lime, generate less sludge and to yield lower metal levels in the effluent.

MINE DRAINAGE AND GROUNDWATER

Mine drainage water, groundwater etc. is treated to remove most of the suspended solids before pumping to surface. The sludge collected is also pumped to surface, and the decanted water drains into the treatment ponds. Studies are still in progress to determine the optimum method to recover the metal values. It also contains 12 ppm NH_3 due to the use of explosives.

SURFACE DRAINAGE REDUCTION

Overburden slopes from rock edges of the pit have been sloped back at 10%. These areas have been revegetated with self propagating grasses. Natural shrubbery and small trees are establishing themselves.

As stockpiles of ore are shipped to the mill and as wasterock is used up for mine backfill, these areas will also be revegetated. The more wasterock is used in underground backfill, the less there will be to generate acid mine drainage.

As ore is removed, the mined out areas are filled with cemented backfill so that when the ore is mined out, most voids will be filled up to the bottom of the pit. When mining operations are completed the mining site will be restored with natural vegetation except for a lake in the open pit. Due to the deep water in the pit it is aimed to make this a habitat for lake trout.

A landscape firm has been retained to revegetate the site:

EROCON LTD.
Timmins, Ontario
Herman Keller - Horticulturist

LIME CONSUMPTION

Lime is delivered in tanker trucks from Reiss Lime Co. in the Toronto area.

Price of lime is C$96/st delivered.

1984 consumption of lime is budgeted at 1100 st.

1984 lime cost is budgeted at C $106,000.

UNDERGROUND SLUDGE

Composition of the sludge settled from water underground is as follows:

Pb	0.31%
Cu	1.36%
Zn	6.27%
Ag	0.3 oz Ag/t

Size distribution

-54 u	98%
-12 u	53%

Flotation tests as a way of recovering the metal values were discouraging. Poor selectivity suggests contamination with oil and grease.

One alternative is to filter the sludge underground in the stopes. Another is to mix it into the cemented backfill. There is limited storage capacity in the creekbed for disposal of the sludge.

TYPICAL ANALYSIS OF MINESITE WATERS

	pH	Zn ppm	Fe ppm	NH_3 ppm	As ppb	Hg ppb
Fresh Water from Feldman Lake	7.0	0.1	0.3	-	-	-
Mine Drainage Water from u/g	8.5	* 0.1	* 0.1	12.4	* 10	* 1
Surface Drainage Water before Lime Treatment	7.3	4.8	0.3	-	-	-
Treated Water in Holding Pond	10.3	* 0.1	* 0.1	1.2	* 10	* 1

EFFECT OF CEMENTED BACKFILL

The strength of concrete roadways underground is noted to have some effect on minewater quality. Because underground minewater is basic it does not attack concrete. $SO_4^=$ ions can be detrimental to concrete however.

Kidd Creek Mines keeps the water content of backfill low. Normal construction concrete needs 600 lb water per m^3 concrete to get 4" - 5" slump. For backfill purposes concrete with 1.9 t/m^3 density is used which equates to only 95 lb water per m^3 backfill.

The conventional setting retardant used in backfill curing cost about 10¢/ton ore. This was replaced with cheaper ligno-sulfonate from the paper industry which frothed badly - a problem that was overcome by adding an anti-frothing agent.

Ground copper smelter slag retards the cement setting rate because the slag lacks tricalcium silicate $(CaO)_3SiO_2$ which is formed in slag only at temperatures above 1250°C and is consequently not used in the Kidd Creek Mine.

The hydration of cement is discussed in the STANDARD HANDBOOK for Civil Engineers pp 3-5. Kidd Creek's backfill practice and technology is discussed by YU and COUNTER (1983).

A source of information and technology for granulation of slag for use in mine backfill is:

National Slag Company
Burlington, Ontario

Telephone (416) 547-2131
Contact Bob Cotsworth, Vice President

CONCLUSIONS

1. Use of cement in backfill has little or no effect on the metallurgical process because the minewater system is not integrated with water supply for the concentrators which are located 15 miles away. No mention was made of metallurgical interference due to chunks of cemented backfill getting into the ore, or even whether this occurs.

2. The site lends itself to establishing an engineered aquatic bog to polish the effluents and help settle any residual suspended solids in summer, but not during the Spring runoff.

3. Straightforward addition of lime to a ditch is not a very efficient way to treat water. Lime consumption could certainly by reduced through use of a somewhat more efficient dosing and mixing system. The total lime cost at C$106,000/year does not leave much of an incentive to install a more sophisticated plant, however.

The Kidd Creek Mine is planning the restoration of the minesite in advance to have minimum impact on aesthetics and water quality. This is in stark contrast with the nearby Kam Skotia Mine which is an example of what happens when such measures are not adopted on a timely basis.

MAIN CONCLUSIONS Copper, lead, zinc concentrating and refining from sulfide ores can be conducted on a massive scale without serious environmental impact. Water treatment using lime only can achieve an effluent where combined heavy metals do not exceed 1.0 ppm.

INTRODUCTION

The Kidd Creek copper-zinc-lead-silver-tin mine in northern Ontario is one of the richest base metal resources ever to have been discovered. Because of unsuitable ground conditions at the minesite, ore is transported by rail to the fine crushing, milling and concentrating plant located 17 miles to the southeast of the minesite in the greater Timmins area.

The mill and concentrator treat 13,000 tons per day of ore to yield zinc, copper and lead-silver concentrates. Zinc is refined on the site using an electrolytic jarosite process and half the copper is shipped to Noranda while the remainder is smelted at Timmins at the Kidd Creek plantsite.

There are several items of interest:

1. The 3000 acre tailings disposal site which uses the Robinsky thickened tailings concept.
2. Disposal/storage of a large volume of pyrite-silver concentrates.
3. Water management at a large integrated mill-concentrator-smelter-refinery complex.
4. Effluent treatment before discharge.
5. Effect of water recycling from tailings to the mill on metallurgical recovery.
6. Effect of thiosalts.
7. Use of cyanide for pyrite depression.
8. Process improvement due to a water temperature increase brought about by slag granulation in the copper smelter.
9. Recent increase in selenium in the tailings effluent.
10. Potential for an effluent polishing marsh.

LOCATION

The Mine is located just north of Timmins, Ontario. The mill is located 17 miles southeast of the mine and 15 miles east of the center of Timmins.

CLIMATE

Continental with heavy snowfalls in cold winters. There is an average net 17" precipitation annually. Temperatures vary from -40°F in January to 75-85°F in July. Snow accumulations in winter range up to 120".

STARTUP

The first mine-mill operation started up in 1966 just three years after the first drill hole indicated copper-zinc mineralization. The second and third grinding-flotation divisions started up in 1967. Further development milestones are:

1970 : Computer control of reagent addition

1974 : Recovery of pyrite-tin concentrates and startup of a tin plant

1974 : The concentrator is fed entirely by underground ore as the open pit is exhausted.

1975 : Recycling of mill water is implemented.

1979 : Startup of a fourth grinding-flotation circuit to treat an additional 3300 tpd bringing total production to 13,300 stpd.

1982 : Startup of a new copper smelter

Flotation

COPPER-ZINC ORE

After primary grinding to 50 per cent minus 325 mesh, the copper-zinc ore is conditioned with lime, sodium dithiophosphate, MIBC and sulphur dioxide. The lime and sulphur dioxide assist in pyrite and sphalerite depression.

Coarse copper recovery is performed in primary roughers operated at a pulp density of 52 per cent solids and a pH of 6.7 (Fig. 2). The primary rougher tailing undergoes secondary grinding to 80 per cent minus 325 mesh, and subsequent conditioning with sodium dithiophosphate before the secondary roughing stage. Following the secondary roughers, sodium dithiophosphate and sodium isobutyl xanthate are added for copper scavenging.

Three stages of cleaning are performed on the combined primary and secondary rougher concentrates and the first scavenger concentrate. Sodium cyanide is added to the first cleaner for additional pyrite depression. Flotation middlings are reground to 98 per cent minus 325 mesh and recycled to the secondary roughers.

The copper scavenger tailing is conditioned before zinc flotation with sodium isobutyl xanthate, copper sulphate, Dowfroth 250 and lime to a pH of 10.0. Zinc roughing is followed by the addition of more sodium isobutyl xanthate before two-stage scavenging. The rougher and first scavenger concentrates undergo three stages of cleaning after conditioning with lime to pH 10.5. The cleaner tailing and second scavenger concentrates are reground to 98 per cent minus 325 mesh, conditioned with sodium isobutyl-xanthate, copper sulphate and Dowfroth 250, and then recycled to the middle of the rougher flotation bank.

The products are a copper concentrate and a low-silver zinc concentrate. Tables 2 and 3 summarize flotation metallurgy and reagent consumption.

The copper cleaner cells are No. 30 Denver DR machines. All other flotation cells are No. 66 Wemco Fagergren machines.

SILVER-LEAD-ZINC ORE

After rod milling, the silver-lead-zinc ore undergoes closed-circuit primary and secondary ball milling to 75 per cent minus 325 mesh (Fig. 3). Copper flotation is conducted at 40 per cent solids and a pH of 7.6. Flotation is preceded by aeration with sulphur dioxide to depress galena, sphalerite and pyrite, and conditioning with sodium isobutyl xanthate and Dowfroth 250. Copper rougher tailing is treated with sodium isobutyl xanthate and Dowfroth 250 before scavenging. The rougher and scavenger concentrates undergo a three-stage cleaning after the addition of lime to pH 11.5. The first cleaner tailing is pumped to the lead-circuit conditioner. Each subsequent cleaner tailing is recycled to the head of the previous cleaning stage.

Copper scavenger and first cleaner tailings are conditioned with sodium dithiophosphate, sodium isobutyl xanthate, MIBC and soda ash in preparation for lead flotation. The soda ash raises the pH to 8.5. The rougher and first scavenger concentrates are cleaned in three stages. The third cleaner tailing

feeds the second cleaner, while the first and second cleaner tailings and the second scavenger concentrate are recycled to the scavenger cells, to which sodium isobutyl xanthate is added.

Zinc flotation of the silver-lead-zinc ore is similar to that of the copper-zinc ore except that pH is maintained at 10.5 in roughing and 11.0 in cleaning to assist in pyrite rejection.

The products are a high-silver copper concentrate, a lead concentrate and a high-silver zinc concentrate. Tables 2 and 3 summarize flotation metallurgy and reagent consumption.

The copper cleaner cells are No. 24 Denver Sub A machines. All other flotation cells are No. 60 Wemco Fagergren machines.

FIGURE 4 — Kidd Creek flotation.

Flotation Control

Flotation grade and recovery are controlled by computer addition of flotation reagents. The reagent control strategy utilizes a computer program to adjust collector addition based on maximum economic efficiency. Copper sulphate addition is based on the zinc content in the zinc circuit feed.

The pH at critical control points is monitored by electrodes immersed in conditioners.

Seventeen continuous samples are required to provide assay information for computer-controlled reagent addition. The sample streams are pumped to head tanks above the X-ray room at a rate of 50 gpm, of which approximately 4 gpm is sampled for X-ray analysis. The overflow from the head tanks is cut once every 20 minutes with a Denver gang sampler for daily wet chemical analysis. Densities of concentrate streams are measured and controlled to improve accuracy of X-ray analysis.

Two ARL PCXQ Model 44000 X-ray units, each capable of handling 15 process streams, assay for lead, zinc, iron and copper concentrations. The X-ray voltages are read by an interface console which provides digital and analog signals to a Modcomp MC II/25 computer. The Modcomp computer converts voltages to assays, and does the necessary calculations to allow pulp densities, assays, recoveries and economic efficiencies to be logged every 12 minutes for copper-zinc ore and every 6 minutes for silver-lead-zinc ore. Alarms resulting from X-ray malfunctions, or out-of-range densities, grades or recoveries are also printed out.

Computer-generated signals for reagent additions are transmitted to a Reagent Interface Panel, where conversion to pneumatic signals for valve control occurs. Four Brooks rotameter control panels with needle valves provide manual flow control when required.

Manually set Moore level controllers control the pulp levels in the flotation banks. The implementation of computer level and frother control is under development to complement the current reagent control strategy.

Mill Control

A central control complex, located between the grinding and flotation sections, monitors and controls all mill functions except concentrate drying. It houses the central control room, the computer room, the rotameter room, the X-ray analyzer room, the instrument repair shop and the shift foreman's office. Plant communications are relayed to and from central control via a public-address system, direct-line and dial telephones, and a VHF linkage is used to communicate between the minesite, railroad, river pump-house and mobile units.

There are eight control panels in the central control room, one each for fine crushing, tin plant, tailings thickener, reagent control and mill services, and three for grinding and flotation. The major equipment items, depicted graphically on flowsheets, are equipped with lights displaying stop, start or fault conditions. Pumps, which must be started locally, are equipped with high-level alarms on their respective pump boxes.

Annunciator alarms indicate high lube oil pressures, bearing and motor winding temperatures, thickener and drive torques, and pressures in gland water systems. Ammeters indicate motor drives and pump loadings. Also present are tonnage totalizers for feed and dried concentrate production as well as pH and density recording at key process points.

Programs responsible for the calculation of X-ray assays, process monitoring and control, and alarm reporting are performed on a Modular Computer Systems II/25 computer. The computer has a memory capacity of 64K words of core storage along with 2.5M words of bulk storage on two Diablo moving-head disks.

All data and alarm messages are logged on KSR-38 and RO-38 teletypes. The system also includes peripherals and a Tectronix CRT to provide access to stored data.

A Centronics line printer, a magnetic tape drive and a second CRT with hard-copy capability are used for on-line programming.

Tin Plant

Pyrite and tin concentrates are recovered by flotation and gravity techniques from the zinc circuit tailing (Fig. 5). The zinc tailing is deslimed to reduce the reagent consumption in the pyrite flotation circuit and then conditioned with sodium isobutyl xanthate and Dowfroth 250. This is followed by a pyrite flotation circuit comprised of roughing, scavenging and three stages of cleaning at pH 10.2. Roughing, scavenging and the first cleaning are performed on No. 600 Denver DR machines; No. 300 Denver DR machines are used for the second and third cleanings. The pyrite concentrate is thickened in Lamella thickeners and impounded for possible future recovery. Coarse silica particles are eliminated from the pyrite tailings by cycloning and elutriation.

A series of 45 Bartles-Mozley gravity concentrators are the first stage in the gravity process. The Bartles-Mozley tailings are discarded, while the concentrate is sent to Holman slime tables for

250,000 st/year	Sulfuric acid

PROCESS

The Kidd Creek concentrator was described by THOMPSON et al. (1978). There are four milling and flotation circuits which treat two main ore types - a copper zinc ore and a silver-lead-zinc ore. The two flotation circuit arrangements are shown below as reported in the CIM book on Canadian Milling Practice. The 1975 reagent consumption is also shown below.

Key flotation reagents used are SO_2 in the front end of the circuit to depress galena, sphalerite and pyrite. Xanthate at pH 7-7.5 floats copper. Dithiophosphate floats galena at pH 7-7.5, finally after addition of lime and copper sulfate to activate the sphalerite, it is floated too.

1. TAILINGS DISPOSAL

Originally a perimeter dike discharge system was employed for tailings disposal, but was revised to incorporate the central discharge of thickened tailings onto a cone as developed by ROBINSKY (1981). Two separate mill tailings products are treated and stored in the tailings area - overall mill tailings and a pyrite concentrate containing silver. The tailings area which comprises three ponds covers 3000 acres and has a rectangular shape.

Kidd Creek Mines employ the Robinsky thickened tailings disposal method. Final mill tailing is pumped 15,000 ft. through two 18 inch pipelines to two 371 ft diameter Dorr-Oliver-Long caisson-type thickeners. The pulp - thickened to 55% solids - is pumped to the spigotting area and discharged so as to build a conical mound in the central tailing area. Thus, the height of the perimeter dike is kept to a minimum.

Outflow from the tailing area is treated with lime before being discharged to a large settling pond where heavy metal hydroxide precipitates are allowed to settle before the decanted effluent is discharged.

By thickening the tailings from 20% solids to around 55% at the disposal site, a considerable amount of water can be reclaimed for reuse, thereby reducing water consumption compared with other tailings systems. About 60% of the water used in the mill is reclaimed from the tailings system.

Source: ROBINSKY (1981)

SCHEMATIC PLAN OF TAILING DISPOSAL AREA.

The ROBINSKY technique reduces the initial capital and operating costs of tailings disposal. Reduced seepage to the surrounding environment and maximum evaporation is claimed. Runoff is also optimized and, according to ROBINSKY (1981) dusting is eliminated. The ROBINSKY system also eliminates the need for high and costly dam walls and dikes.

The principle of his design is to discharge thickened tailings from a central point in the tailings impoundment. The tailings flow outward thereby forming a cone with about 6% slope from the center. Thus, more material can be disposed of in the same surface area than when peripheral discharge is employed. Critics of this technique point out the dangers of thixothropic tailings in an earthquake. ROBINSKY counters this by pointing out that in earthquake zones a shallower slope of 4½° can be used. Earthquake effects tests have been simulated by Geotechnical Engineers Inc., Winchester, MA, but, in any case, the Timmins area is a stable continental shield area and not earthquake prone.

This system of tailings is described by ROBINSKY (1981). During a visit to the Kidd Creek tailings site in 1984, there was no apparent dust problem. A recent rainfall had dampened the tailings surface. Plant personnel indicated, however, that during spells of dry weather a considerable amount of dust is generated to the extent of presenting unpleasant conditions when the wind blows toward the plant. Certainly a very large surface area of tailings is presented and a freeze drying surface effect would be expected in winter. The designer claims that since the tailings do not segregate by particle size to the same extent after thickening, capillary rise will be maintained due to the clay particles which should allow the surface to remain wetted.

Although this area may be more compact as claimed, a fair degree of channelling was observed on the surface flow. Also, since the whole surface of the impoundment is active for the full life of the project, it does not present an opportunity for progressive restoration of the area. Restoration must wait until the end of the life of the project when the whole area must be restored in one shot.

Cyanide is used to depress pyrite in the flotation sequence and when the tailings are spread over the thickened tailings cone there is a lot of exposure to sunlight and wind to degrade any residual cyanides. However, cyanide in these tailings is most unlikely to be a problem whatever the tailings system.

More information about the ROBINSKY thickened tailings system can be obtained from:

TAILINGS THICKENER AT KIDD CREEK CONCENTRATOR

THICKENED TAILINGS CENTRAL DISCHARGE POINT

CENTRAL DISCHARGE FOR PYRITE TAILINGS

FINAL DISCHARGE & RECYCLE WATER PUMPHOUSE

LIME TREATMENT AND SETTLING STATION

During the 1984 visit to the site, it was noted that problems have been experienced with a leak in one of the caisson tailings thickeners. Concrete tailings lines have been replaced by schlairpipe (polyethylene) lines and the operators were struggling with line blockages and pipe bursts for reasons that were not established.

Because pyrite has been separated (90% recovery) from the bulk of the tailings, the potential for acid mine drainage from this impoundment will be much reduced (but not eliminated). This will make the final restoration and revegetation of the tailins impoundment a lot easier,

2. DISPOSAL/STORAGE OF LARGE VOLUMES OF PYRITE CONCENTRATE

A 33% pyrite concentrate is separated in the flotation circuit and pumped to a second thickened tailings impoundment with a central discharge point. Although THOMPSON et al. (1978) refer to lamella thickeners for the pyrite, none were observed during the plant visit in 1984. It is believed that pyrite being so dense, settles readily and dewaters in a cone shaped tailings pile allowing decant water to be collected on the periphery of the impoundment.

The pyrite concentrate contains about 2.3 oz Ag/st and is the subject of a project to determine the best metallurgical approach. Apparently about 1 ounce of silver per ton can be leached by conventional cyanidation.

The final disposition of the pyrite concentrate is still not clear. It is possible that these will one day be treated to recover silver in the future if a profitable process can be developed, at which point the pyrite will be disposed of in a permanent fashion.

A cursory inspection of the pyrite concentrate, stockpiled using the Robinsky central discharge method, revealed that the surface of the pyrite was stable enough to walk on. Surface oxidation was occurring as was evidenced by the fact that the odor of SO_2 could be detected in the air and even the cattails in the peripheral decant water ponds appeared to have a struggle staying alive.

While on the one hand the pyrite tailings have been segregated into a smaller (but still extensive) impoundment than the main tailings, reducing the potential for acid mine drainage from the main impoundment, there remains the question of potential for acid mine drainage generation from the smaller pyrite concentrate impoundment.

At this point in time while the plant is still in operation and the tailings are still active, AMD is not a problem at this site. The question only arises with respect to ultimate disposal of the pyrite. In this respect, possibly the Robinsky central discharge concept has some advantages if the peripheral ponds can be limed or covered in ground limestone

and converted to a large aquatic ecosystem designed to clean up the AMD that would collect in them. Being located in the perimeter of the impoundment, the potential exists to create a very large engineered bog to filter out metal hydroxides with hopefully minimal maintenance needs.

According to MARSHALL (1979) the water that decants from the pyrite concentrate impoundment contains up to 14 ppm Zn, but this solution drains to a lime station after which it mixes with decant from the main tailings area.

SULFIDE TAILINGS DISPOSAL STUDY

CANMET is undertaking an industry cooperative study to develop improved ways of disposing of sulfide mine tailings. Sponsors of the study include:

COMINCO	Walter J. Kuit
NORANDA	Bruce Wallace
KIDD CREEK MINES	Colin Chapman

3. WATER MANAGEMENT AT A LARGE MILL-REFINERY-SMELTER-TAILINGS COMPLEX

At the Kidd Creek mill site there are four milling and flotation sections, a zinc roaster and electrolytic refinery, a copper smelter and two acid plants.

The Kidd Creek metallurgical facility is located in a net precipitation climate which means that zero discharge is not a reasonable goal. To treat 13,000 tpd ore, a total of 11.50 mm US gallons of water is discharged to the Porcupine River. (43,560 m^3/d = 3.60 m^3/ton ore)

About 9,500 US gpm (51,800 m^3/d) fresh water is drawn from the Frederickhouse River and 9000 US gpm (49,000 m^3/d) is reclaimed from the tailings area decant system for use in the concentrator and the copper plant. Four pumps installed at the Frederickhouse River can deliver up to 10,000 igpm water through a 5 mile 28 inch Ø corrosion protected all welded steel pipeline to a 750,000 gallon raw water storage tank.

FIGURE 6

METALLURGICAL SITE WATER FLOWSHEET

TEXASGULF CANADA LTD.

METALLURGICAL SITE
SCHEMATIC OF WATER USAGE
AND LIQUID EFFLUENTS

LAFOREST et al. (1983) make the statement,

> "Since 1975 water conservation at the metallurgical site has been given high priority. With the expansion of existing facilities and the construction of the new copper smelter, a complete study was made of anticipated water usage to determine the most effective method of minimizing our water consumption. From this study a new water flowsheet for the site was developed. This led to the construction of a pumphouse to recycle water from our tailings ponds and the use of cooling towers to recycle water from the Hazlett casting machine, acid plant coolers, compressors, furnaces and the converting slag granulation. Slag granulation water is returned to the concentrator where the higher temperature further improves metal recovery."
>
> "The implementation of this new water distribution system has significantly decreased the fresh water requirements, reduced the amount of effluent discharged into the Porcupine River and minimized capital expenditures for the water management system expansion."

The 1982 water balance for the metallurgical site was:

Fresh water	6.9×10^6 US gpd	26,136 m^3/d	2.16 m^3/t ore
Recycle water	7.5×10^6 US gpd	28,410 m^3/d	2.34 m^3/t ore
Discharge *	11.5×10^6 US gpd	43,560 m^3/d	3.60 m^3/t ore

* Discharge includes surface runoff from the 3600 acre drainage area.

Use of 2.16 m^3 fresh water per t ore treated (which includes both milling flotation, tailings discharge and the smelting and refining operations including the acid plants), is relatively water efficient. In the Kidd Creek climate, water is not exactly a scarce commodity and the general principle of "The amount of water needed for a metallurgical facility is proportional to the amount available." is indicated.

Nonetheless, the discharge of a further 3.60 m^3/t ore treated to the Porcupine River indicates that there is a significant potential to recycle considerably more water - possibly avoiding the need for any fresh water from the Frederickhouse River. However, in considering the overall achievements with respect to environmental control at the site and reported analysis of the effluent, there would not seem to be an economic incentive to recycle more water which would increase pumping costs and might require some additional water treatment steps to make reclaimed water more suitable for all uses in the plant.

A degree of macro-recycling occurs in that water discharged to the Porcupine River eventually returns via Nighthawk Lake to the Frederickhouse River from which the plant draws its fresh water. Ultimately the Frederickhouse River flows north into James Bay.

ZINC & COPPER PLANT PROCESS WATER AND POTABLE WATER

A plant treats 3200-3600 US gpm of raw water for zinc plant consumption and potable water for the whole facility.

Raw water is first clarified in a 60' Ø x 15' straight Ecodyne reactivator followed by six sand filters. Sand filter discharge is stored in a 1.25 million gallon storage tank, and is used for plant service water.

Service water also provides feed to the demineralizing train which produces process water and boiler feed water.

Demineralized water is generated by ion exchange for leaching the zinc calcine as the electrolytic process is sensitive to metal impurities other than zinc.

ZINC PLANT WATER MANAGEMENT

All waste water and drainage water from the zinc plant area is collected in an effluent recycle pond and recycled for process water in the zinc plant. This pond also collects any contaminated drainage water from the new copper smelter. A neutralization plant and clarifier have been installed to treat any excess water and to return it to the concentrator for use or disposal through the tailings system. The liquid effluent from the containment pond for "jarosite" (mainly iron hydroxide but rich in zinc and other metals) is returned to the zinc leaching plant for recycling as process water.

COPPER SMELTER WATER MANAGEMENT

Water requirements for the copper smelter are primarily for cooling, temperature control of the furnaces, slag granulation and treated feedwater for the waste heat recovery boilers. All water used by the copper smelter and refinery operations is contained, recycled internally or recycled through the concentrator.

JAROSITE POND

The jarosite and neutralized solids ponds were modelled after the central discharge tailings area. Jarosite is discharged from selected points along the center dike separating the two ponds.

Originally the rate of neutralized solids production was expected to be about half of the jarosite production. Hence, the total pond area is divided 1/3 for neutralized solids and 2/3 for jarosite. By discharging evenly from both sides of the central discharge dike, this dike would be supported by solids building up equally on each side. However, neutralized solids production was dramatically reduced early on by recycling the

neutralization thickener underflow to the neutralizing circuit. Consequently a gravel counterbalancing berm had to be constructed along the central dike.

The jarosite pond is lined with natural clayey material that occurred at the site and according to SWEET (1980) the buildup of jarosite increases the impermeability.

Jarosite pond water typically analyses :		
	pH	2.7
	zinc	9300 ppm
	iron	100 ppm
	copper	100 mg/l
	lead	1.1 mg/l
	cadmium	46 mg/l

The perimeter dikes are designed to minimize any seepage of this water to the surrounding swamp. SWEET (1981) discusses the design of the jarosite pond and the neutralization solids pond, and provides several interesting comments on the design of such installations.

FIRE WATER SYSTEM

The plant's fire water pumps are also located at the main pumphouse located at one of the two 750,000 gallon (3000 m^3) water tanks. If necesary the fire fighting pumps can draw water from both storage tanks to supply five water mains, hydrants and sprinkler systems.

4. EFFLUENT TREATMENT BEFORE DISCHARGE

Clear decant solution from the peripheral collection system of the tailings site is treated with lime and then collected in a large holding pond. About 1800 tons per year lime is used to treat an average flow (including runoff) of 14,000-15,000 US gpm (75,000-80,000 m^3/d) of water.

Lime addition is controlled to keep the zinc level below 0.3 ppm which it is found equates with total heavy metals generally under 0.5 ppm to meet the 1 ppm guideline requirement.

At the discharge point from the holding pond, a pumphouse with 3 pumps capable of recycling 9000 gpm (5000 m^3/d) through 24" schlairpipe has been installed, to feed the 750,000 gallon storage tank at the concentrator. Water that is not recycled overflows the intake chamber for the recycle pumps and is discharged through a weir to the Porcupine River. Discharge varies from almost nothing to 20,000 gpm (109,000 m^3/d). The use of a plastic reclaim water line and plastic coated storage tank and FRP internal piping avoided many of the corrosion problems that can occur when reclaim water is used.

Although the tailings thickener overflow is discharged to the perimeter pond around the tailings pile at pH 9-10, oxidation of thiosulfate in summer results in a pH drop to 3.5-4.0. In winter, however, the pH drops to around 7 by the time the water reaches holding pond "C" ahead of the lime station.

PROVISION FOR SPRING RUNOFF - HEAVY RAINFALL

During spring runoff, or if there is an unusually heavy rainfall, the catchment pond around the plant might overflow. Overflow water is then collected in a drainage ditch, collecting uncontaminated surface drainage water from the concentrator and service building areas. This water is then directed through a culvert to pond "D" where it is mixed with lime and treated water from #1 lime station.

Some years ago the area experienced a phenomenal deluge known as "the Timmins Storm" which is now used as the standard for tailings impoundment design in northern Ontario.

ENVIRONMENTAL CONTROL AND MANAGEMENT

An important part of the management of water in a large integrated mill-tailings-concentrator-refinery-smelter system is the control of the environment. An important aspect of environment control is the quality of water that is discharged as an effluent.

LAFOREST et al. (1983) have successfully shown how air pollution control and water pollution control are interrelated. Through very good air emission control, the distribution of heavy metal particulates over the site and drainage area is kept to a minimum. This undoubtedly has as much of a positive influence on the quality of aqueous effluents from the site as the management of water quality per se, especially one with a 3600 acre drainage.

In order to manage the quality and quantity of the final discharge from the site holding ponds, measuring and sampling stations and treatment facilities have been incorporated into the design of the tailings impoundment area. The final discharge is monitored on a daily basis for pH, suspended solids and dissolved heavy metals concentration. In addition, individual effluents from the plant are spot sampled at source to detect abnormal conditions.

The following Table shows a six year analysis summary of the final effluent and indicates that no significant differences have occurred in the water quality since startup of the copper smelter. The cumulative concentration of heavy metals is well within the guideline of 1 mg/l.

WATER QUALITY MONITORING
ANALYSIS OF FINAL EFFLUENT

	Flow m^3/min	pH	S/S mg/l	Copper mg/l	Lead mg/l	Zinc mg/l
1982	30.2	8.4	10	LT 0.1	LT 0.1	0.3
1981	30.9	8.4	10	LT 0.1	LT 0.1	0.1
1980	31.4	7.6	20*	LT 0.1	LT 0.1	0.3
1979	30.6	7.2	10	LT 0.1	LT 0.1	0.3

1977	19.2	6.7	10	LT 0.1	LT 0.1	0.5

LT = less than

* Suspended Solids in the fresh water intake frequently exceed the 15 mg/l guideline that Kidd Creek effluent must meet.

Clear peripheral decant solution is treated with lime to reduce the zinc content to 0.3 ppm before the solutions flow to a large holding dam.

BIOLOGICAL SAMPLING

LAFOREST et al. (1983) describe a diverse biological program at Kidd Creek's metallurgical plant. The program consists of benthic fauna sampling, bioassay testing, mossbag surveys, rain, snow, soil and vegetation sampling. A buffalo herd is maintained immediately adjacent to the south boundary of the metallurgical plants as a token of the company's continued desire to be a good citizen.

Benthic fauna surveys are conducted on the Porcupine River system to examine the impact of Kidd Creek's tailings discharge on bottom dwelling organisms. Such surveys have been conducted since 1971 at various locations upstream and downstream of the tailings discharge. Water quality can be assessed by the presence and relative abundance of certain indicator species which are known to be sensitive, moderately tolerant or tolerant organisms. Results over the last twelve years indicate that the effect of so large a metallurgical plant on the aquatic environment has been minimal.

Although slight increases in sulfates, total solids, total hardness, calcium and zinc concentrations are noted immediately downstream from the discharge, these concentrations return to normal levels within four kilometers of the discharge. The fact that similar populations of macroinvertebrates are found upstream and downstream of the discharge indicates that the tailings discharge has no lasting significant effect on the Porcupine River system.

TYPICAL ANALYSIS OF METALLURGICAL SITE WATER

LOCATION OF WATER SAMPLES	pH	Total Solids ppm	Susp. Solids ppm	Sulphates ppm	Ca ppm	Fe ppm	Cu ppm	Pb ppm	Zn ppm	NH_3	HG ppb

SOURCE: MARSHALL (1979)

Bioassay Testing

The 50% survival requirement for rainbow trout in the static 96 hour bioassay test has consistently been met since 1977 when the tests were started according to LAFOREST (1983). Apparently, since their paper, there was a short period during which the LC50 96 hour test was marginal, but this was suspected as being the result of faulty trout from the hatchery. Nonetheless, since then, the LC50 test results have returned to normal.

Mossbag Surveys

Mossbag surveys were started in 1980 and are a relatively new means of monitoring airbourne heavy metals deposition. Heavy metals are efficiently adsorbed and retained on moss by an ion exchange process in amounts directly proportional to exposure regardless of meteorological conditions, and are used as semi-quantitative indications of heavy metals in the atmosphere.

Mossbags have distinct advantages over vegetation sampling because moss is similar to epiphytic organisms in that the possibility of contamination via root uptake is eliminated. The method is described by LAFOREST et al. (1983).

The Mossbag results indicate a pattern of copper, zinc, lead, iron, cadmium and arsenic fallout around the metallurgical site which return to background levels within 2 km. Levels of 4000 micrograms copper per gram of moss per month are, however, measured in the immediate proximity of the copper smelter.

Kidd Creek Mines Ltd. designed their operations with environmental protection in mind even before effluent treatment was a regulatory requirement. Perhaps because the operation has had such a good track record in the past, people at the Kidd Creek operation are more aware of their company's interest, than they are of the details.

5. EFFECT OF WATER RECYCLING FROM TAILING TO THE MILL ON METALLURGICAL RECOVERY

Based on data provided by MARSHALL 1979) the water draining from the main tailings area before and after liming has the following composition:

	Before Liming	After Liming
pH	2.7	6.0
TDS ppm	950	995
S/S	2	8
$SO_4^=$	875	771
Ca	-	-
Fe	LT 3.0	0.3
Cu	LT 0.1	LT 0.1
Pb	LT 0.1	LT 0.1
Zn	LT 0.3	0.1
NH_3		0.5
Hg ppm		LT 1.0

Water is recycled to the mill after liming. The TDS of this water is relatively low at 995 ppm, and although the $SO_4^=$ is 771 ppm and calcium and magnesium levels not shown, it appears that these are low enough not to be a major concern in the flotation separation and recovery of sulfides. Although 60% of the water used in the concentrator comes from the tailings water reclaim station, it must be remembered that it is significantly diluted by precipitation and that it has been neutralized and aged prior to return to the plant.

$SO_4^=$ apparently in the levels encountered does not seriously affect flotation performance at Kidd Creek. $SO_4^=$ balance is however critical in the electrowinning tankhouse. $SO_4^=$ is bled from the system with jarosites. CHAPMAN (1985) confirmed that recycle water quality has no noticeable effect on metallurgical recovery.

$S_2O_3^=$ (thiosulfate) generated through SO_2 addition is needed to achieve a selective copper float after the grinding step. The $S_2O_3^=$ depresses pyrite and sphalerite.

The presence of sulfate and carbonate (the latter due to carbonate addition as soda ash) will precipitate lead from solution effectively.

PERMITTING

In 1984, effluent and operating permits at both the mine and metallurgical plant sites were reviewed and approved without changes. This is an indication that the regulatory authorities are satisfied with the measures adopted at the site.

ULTIMATE DESTINY OF HEAVY METALS

Kidd Creek Mines Ltd. sell their anode slimes after these have been deleaded. These contain up to 45% Ag, under 5% Pb, 30-45% Se and 1% Cu. The slimes are sold to processors in Europe and to Noranda.

Heavy metals and indium are also tied up in the jarosites. Flue dusts containing indium, cadmium, copper, lead, zinc and silver are generated.

Precipitated heavy metals as hydroxides are left in the tailings material and in the settling pond after the lime station.

Cadmium leaches from the calcine with zinc and is precipitated from solution using zinc dust ahead of the electrolytic tankhouse. This drops cadmium from about 0.02% in the electrolyte. The precipitated cadmium sponge is treated to yield a cadmium product.

6. THIOSALTS

Tailings are discharged to the Robinsky impoundment system at pH 9-10. By the time the solution decants to the lime addition plant, it has dropped to pH 7 in winter and pH 3.5 in summer, presumably due to oxidation of thiosulfate. After lime addition to pH 10.5, the decant solution is aged in a holding pond where the pH drops again and in which metal hydroxides settle out.

7. USE OF CYANIDE FOR PYRITE DEPRESSION

Sodium cyanide is believed to be used for pyrite depression in the zinc flotation tailings. However, to be effective for this purpose only a small dose would be needed. Using computerized control of the flotation circuits, cyanide addition is very carfully controlled based on the amount of pyrite left in the zinc concentrate. Cyanide is added to achieve a surface effect so the cyanide is tied up on the solid particles. If there is any residual cyanide in solution it would likely be removed from solution on the Robinsky tailings over which the solution decants in a thin layer. More likely cyanide will be "fixed" on the particle surfaces.

8. PROCESS IMPROVEMENT DUE TO WATER RECYCLING

When water temperatures drop, it is believed by the operators that copper recovery drops. Although there is no firm data to prove this, it is believed that when the copper smelter slag granulation water is recycled to the flotation plant that the slight increase in temperature results in an improvement in recovery.

600 tpd of granulated slag is generated. Originally this was to be ground and used to substitute for cement in the backfill. However, because of the way it is made and the composition (low Ca and Ferrous^{++}) it does not have the anticipated pozzolonic effect. The slag is now used to construct berms for the tailings dams.

9. SELENIUM

Recently, selenium levels in the ore have increased. Selenium occurs with pyrite, mainly in the copper minerals, and with the sphalerite in solid solution.

Apparently selenium levels in the final effluent have been reaching levels around 0.3 ppm which have made it necessary to start seeking ways to remove it.

One method under review is to intercept the smaller effluent stream in the plant that is the main contributor of selenium so that this source of selenium can be removed.

One or two methods for selenium removal from solution are discussed in the volume on Contaminant Removal.

SEWAGE

There are two sewage treatment plants on the metallurgical treatment facility. The sludges from the septic system are occasionally pumped with the tailings to the pond but the volume of this material is not enough to make an impact.

10. POTENTIAL FOR EFFLUENT POLISHING MARSH

Although base metal level averages in Kidd Creek effluent discharge meet the regulated limits, no data on day-to-day analyses were reviewed. Physical examination of the site and treatment system indicated that the simplest of lime addition systems is employed. The site is located in an area of flat swampy land which would lend itself ideally to the development of a large meander system with an engineered bog in which aquatic plants and algae could be grown to polish the effluent. Such a bog would, of course, be functional in summer only. It would serve to remove suspended metal hydroxides and potentially also remove dissolved metals through metabolic uptake. In addition, as the ecological system recycles over several seasons the rotting vegetation in the lower levels will generate small amounts of "marsh gas" H_2S which can be expected to precipitate metals to lower levels still as sulfides. Examples of such working bogs are to be found at AMAX's Buick Mine, a St. Joe Minerals mine in New York, and at Falconbridge, Ontario.

BRIERLY et al. (1984) discusses partial biological removal of Selenium from acidic uranium mill effluents in New Mexico. It is expected that there would be a good chance that selenium would also be polished - possibly more effectively - by a mature aquatic bog system. This is a RANDOL speculation, however, based on the fact that selenium is efficiently polished by sulfide addition even though it does not itself form a sulfide.

INTRODUCTION

When AMAX discovered the Mount Emmons molybdenum orebody in the 1970's, it was expected to bring it into production. In order to gain access to the ore to draw a bulk sample for metallurgical testing, AMAX acquired the adjoining zinc mining property known as the Keystone Mine. This mine had ceased operation some years before, but the site was in need of reclamation.

When AMAX purchased the Keystone Mine, they inherited all the environmental problems of the property including four tailings ponds and acid mine drainage from the workings above. The tailings ponds were unstable, and in fact one had failed.

After stabilizing the Keystone site, a water treatment plant was installed to treat water from the Keystone operations.

The $12-14 million spent on site stabilization and water treatment is relatively small compared with the $700-800 million expected investment for mine development. For its current job, the plant may be excessive, but at the time it was installed, it was a demonstration of exceptional commitment to improve water quality from the site in support of the planned development of a new molybdenum mine.

AMAX's work at Mount Emmons has involved the reclamation and revegetation of the Old Keystone Mine and tailing pond complex. A water collection and treatment system utilizes the heavy metals removal plant seen at bottom right.

The molybdenum ore body, which AMAX proposed to mine, lies 1200 feet below the square-topped summit of Mount Emmons.

After installing the water treatment plant, the decision to proceed with development of the molybdenum mine and mill was put on hold. The water treatment plant continues to treat water from the Keystone mine site as described below.

The Mt. Emmons water treatment facility is of interest for several reasons:

1. It is the most recent AMAX water treatment installation incorporating the SWIFT LECTROCLEAR flotation process to remove precipitated metal sludges by special coagulation around gas bubbles and microfiltration. It provides insight into the performance of a third generation plant design of this type.

2. It is an example of the kind of capital investment required for water treatment if the decision is made to "go whole hog" to satisfy environmental pressures.

3. Before the AMAX site reclamation and water treatment plant was installed, the receiving water, Coal Creek Canyon, was a dead stream. Today it supports trout.

4. The application of LECTROCLEAR flotation is a demonstration of a successful adaptation of a process developed for one industry (meat packing waste removal from effluents) to another.

5. Zinc is reduced from 125 ppm to 0.05 ppm Zn in this plant i.e. 99.96% removal which is an excellent performance.

Items of special interest at the facility are:

- Performance of the Swift Lectroclear process.
- Belt press dewatering of heavy metal sludges.
- Cement stabilization and disposal of sludges.
- General management philosophy and safeguards against performance failure.

This plant received the National Environment Industry Award for the Application of Advanced Environmental Technology in 1981 and 1983.

PLANT LOCATION

The Keystone Minesite is now known as the Mount Emmons operation of Climax Molybdenum Company and is located 3½ miles up Coal Creek from the town of Crested Butte, Colorado, at an altitude of 11,000 feet.

CLIMATE

High altitude Rocky Mountain climate with heavy snowfalls and snow cover from late October to May. Some years experience in excess of 400" snow.

CAPITAL INVESTMENT

Site reclamation, stabilization of existing tailings pond, appropriate drainage diversions, etc., cost $1.9 million.

The water treatment plant required an investment of a further $10.9 million.

OPERATING COST

$750,000 - $1 million per year

DESCRIPTION

1. Four existing Keystone Mine tailings ponds were reclaimed. The dam walls were strengthened; the tailings were covered, contoured, and seeded. Seepage from the four ponds is collected via a series of underground pipelines to a central pond.

   All four of the original tailings ponds were covered with minewaste from exploratory drifting during the evaluation of the molybdenum deposit. The wasterock was rich in clays, particularly bentonite. A geotexile covering was placed over all four tailings sites. Three of the sites were then covered with soil, lime, fertilizer, and sewage sludge and reseeded. Tailings dam No. 4 was compacted for use as a yard and storage area after the surface was sealed. Seeding was carried out using a hydromulcher.

   Surface drainage from undisturbed and/or reclaimed areas is collected by appropriate contouring and is discharged to the creek bypassing the water treatment plant.

   The reclaimed tailings dam toedrain seepage is collected at a rate of 0-150 gpm. It has a pH of 2.5-4.0 depending on seasonal dilution effects. This water has a high heavy metals content including, typically, 125 ppm Zn.

2. The Old Keystone Mineworkings

   All mine buildings were removed and the site cleared except for the few that were needed for maintenance and for the exploration operation.

Mine drainage leaves the excavations at a single point where flowrate is measured across a Parshall Plume. Flowrate of minewater varies between 180 and 540 gpm (540 gpm is the maximum measured since 1981).

This water has a total heavy metal loading ranging between 380-800 ppm.

The original Keystone water collection dam used to hold water with 9,000-12,000 ppm TDS and is very high in heavy metals.

This pond was enlarged and sealed. It has a capacity of 8 acre feet.

This pond presently serves as an emergency surge pond for seepage collection from the tailings ponds, and its contents are gradually blended into the water treatment plant feed.

An interceptor canal was constructed along the entire northern edge of the affected area to intercept and divert hillside runoff water, which is now discharged via a drop station at a point downgrade from the heavy metals pond into Coal Creek.

3. Water Management System

The water treatment consists of the following:

- Parshall Plume flow measurement station.
- Concrete lined settling ponds to drop grit from mine drainage.
- Concrete lined equalization ponds fitted with an air sparging system.
- Heavy metals removal plant described in detail below.
- Sewage plant.
- Retention pond with bypass possibility to Coal Creek.
- Pumps and pipelines to divert treated water to the surge pond if it does not meet effluent discharge limits.
- A potable water supply.

DISCHARGE PERMIT

Since the Mount Emmons plant discharges to a river, an NPDES (National Pollution Discharge Elimination Service) permit is required. The State of Colorado administers the NPDES discharge permit on behalf of the EPA. This is done by the Colorado Department of Health.

These limits are shown in the following table. It is clear that for some elements, e.g., As (0.05ppm), Cadmium (0.015 ppm), and Mercury (0.05 ppb), these limits are very low indeed.

The residual chlorine limit at 0.002 ppm is also very low.

The levels set for the limits are based on ambient levels in the Rocky Mountain streamwater which for some elements are below detection limits achievable by routine analytical techniques.

FLOW CONTROL

Initially there was only a very small retention dam at the Keystone Mine site. Included in the implementation of the wastewater management system was the provision of additional surge capacity to even out flows subject to treatment as a result of precipitation and/or snowmelt. However, due to limited areas available for this surge capacity, the treatment plant itself can accommodate a range of flows from 220 to 2200 U.S. gpm of which the mine drainage is the greatest and most variable contributing flow. Interestingly enough, the minewater flowrate peaks in July, about one month after the spring runoff.

FLOW MEASUREMENT

A 9" Parshall Plume is located at the degritting pond at the head of the process. It is fitted with a Robertshaw Level Probe.

PLANT CAPACITY

The Mount Emmons plant was designed to treat 2200 U.S. gpm and to handle a flowrate varying from 220 to 2200 U.S. gpm. The highest flow rate that it has handled to date has been 1750 gpm although the operators believe it could handle 2000 gpm.

When the flow rates reach their maximum, the metal loadings drop--this helps.

The primary constraint in plant capacity is sand filtration which can become clogged if the flotation cells are not operating at peak performance.

The flotation units were designed for 97% metal removal at design feedrate with 1000 ppm TDS. After installation, the best achievable was 97% solids removal from 480 ppm TDS. Subsequent innovations allowed 98% solids removal at 700 ppm solids.

At low flow season the plant can be shut down for one shift. During high flow season, all units may be operated as necessary for 24 hours a day, seven days a week.

EFFLUENT LIMITATIONS AND MONITORING REQUIREMENTS

During the period beginning immediately and lasting through June 30, 1984 the permittee is authorized to discharge from outfall serial number 001, the final outfall from the wastewater treatment facility as referenced in Figure 2, page 20 of this permit.

1. Effluent Limitations

Effluent Parameter	Discharge Limitations			
	Maximum Weight kg/day (lbs/day)		Maximum Concentration mg/l	mg/l
	30-day avg. a/	Daily max. b/	30-day avg. a/	Daily max. c/
Flow - m^3/Day(MGD)	N/A	N/A	N/A	N/A
Total Suspended Solids	N/A	N/A	20	30
Total Dissolved Solids g/	N/A	N/A	N/A	N/A
Total Arsenic	N/A	N/A	N/A	0.05
Total Cadmium	N/A	N/A	N/A	0.015
Total Residual Chlorine h/i/	N/A	N/A	N/A	0.002
Total Copper	N/A	N/A	N/A	0.04
Total Iron	N/A	N/A	0.5	1.0
Total Lead	N/A	N/A	N/A	0.15
Total Manganese	N/A	N/A	0.5	1.0
Total Mercury j/	N/A	N/A	N/A	0.00005
Total Molybdenum	N/A	N/A	1.0	2.0
Total Zinc	N/A	N/A	N/A	0.6

Oil & Grease shall not exceed 10 mg/l in any grab sample nor shall there be a visible sheen.
The pH shall not be less than 6.5 standard units nor greater than 9.0 standard units c/

There shall be no discharge of floating solids or visible foam in other than trace amounts. Any untreated overflow which is discharged from facilities designed, constructed, and operated to contain or treat as applicable all process generated wastewater and the surface runoff to the treatment facility from a 10-year, 24-hour precipitation event shall not be subject to the limitations set forth in this section. The 10-year, 24-hour precipitation event for this facility is 2.4 inches. The official precipitation gage station identified with the facility shall be Crested Butte Index No. 1959. The permittee has the option of operating and maintaining a precipitation gage at the facility.

EFFLUENT LIMITATIONS AND MONITORING REQUIREMENTS (Continued)

2. Monitoring Requirements

In order to obtain an indication of the probable compliance or non-compliance with the effluent limitations specified in Part I, the permittee shall monitor and report all effluent parameters at the following required frequencies.

Effluent Parameter	Measurement Frequency d/e/	Sample Type f/
Flow - m^3/Day (MGD)	Daily	Continuous
Total Suspended Solids	Weekly	Grab
Total Dissolved Solids g/	Monthly	Grab
Total Arsenic	Monthly	Grab
Total Cadmium	Monthly	Grab
Total Residual Chlorine h/ i/	Weekly	Grab
Total Copper	Monthly	Grab
Total Iron	Weekly	Grab
Total Lead	Monthly	Grab
Total Manganese	Monthly	Grab
Total Mercury j/	Monthly	Grab
Total Molybdenum	Monthly	Grab
Total Zinc	Weekly	Grab
Oil & Grease	Daily	Visual Observation
pH	Daily	Grab or In-situ

Self-monitoring samples taken in compliance with the monitoring requirements specified above shall be taken at the following location: at the final outfall from the treatment plant as referenced in Figure 2, page 20 of this permit.

FEED TO THE TREATMENT PLANT

During the week immediately prior to the Randol visit, feedwater to the treatment plant contained 705 ppm suspended solids.

Blended feed to the plant is not routinely analyzed but rather the individual streams. Data for 1982 ranges on the influent streams were provided as follows:

		Mine Discharge	Tailings Seepage
Flow Rate (USgpm)		180 - 540	0 - 140
pH			
Fe	ppm	27 - 43	700 - 800
Zn	ppm	10 - 115	150 - 300
Mn	ppm	6.5 - 79.0	400 - 500
Cu	ppm	3.0 - 8.2	
As	ppm	Trace	1 ppm
Cd	ppm	0.42 - 0.70	1 ppm
Mo	ppm	LTDL	LTDL
Pb	ppm	0.8 - 1.0	
Hg	ppm	not measured	not measured
TDS	800	- 1000	6 - 7,000

LTDL = Less than detection limit.

The main precipitate forming metals in the feed streams are manganese, zinc, and iron.

WATER TREATMENT PLANT AND PROCESS

- Incoming mine water at pH 2.5-3.5 arrives at an outdoor retention pond.

- The water next passes via a Parshall Plume to one of two degritting ponds connected in parallel to drop as much suspended solids from the water as possible.

- Decanted overflow from the degritting ponds next enters an equalization pond where various waters are mixed. An air sparging system provides air induced oxidation and prevents freezing in winter. Originally hydrogen peroxide was added to oxidize iron, but it has been found that air induced oxidation works more reliably. There was a problem with the feeding system for H_2O_2 addition. The water is thoroughly mixed at this point, still outdoors. All iron is oxidized to the ferric state before lime addition.

- pH of the feed stream is raised to around 10.6 by lime addition in a 12,000 gallon mechanically agitated tank located inside the plant building. Typical flowrate is 400 gpm. All iron at this point is precipitated as ferric hydroxide.

- The lime precipitated dilute slurry is next coagulated in cells operated at up to 5000 amps after addition of Nalco 8815 surfactant. The surfactant modifies the surface tension and results in smaller air bubbles in the next step - Electroclear flotation. Dosage of NALCO 8815 is 1.5-3.5 ppm depending on the solids loading. At the coagulant cell overflow weir 1-3 ppm Percol 278 Allied Colliods Cationic Polymer flocculant are added. Nalco 8815 costs $1.61 per pound, and annual costs for this surfactant amount to $5000.

  The coagulated feed passes over a Parshall Plume and is next fed to one or more of the three Swift dissolved air microflotation basins. Two of the Swift Lectroclear cells have 750 U.S. gpm capacities, and the third has a capacity of 550 U.S. gpm for a total of 2000 U.S. gpm.

- Precipitated solids are removed in floated skimmings at 2-3% solids.

- The solution now containing less than 2 ppm solids is dosed with a further 8 ppm polymer via an automated system, then filtered through downflow gravity flow sand filters. These are open top gravity flow tanks which contain 42.5 tons of media in each filter.

- The filter clarified water goes to a clearwell. Some is drawn off for use as glandwater for the pumps. The rest passes across a rectangular weir so flowrate can be measured and recorded.

- Flowrate and pH measurement signals automatic acid dosing to adjust pH to within the discharge limits of 6.5-9.0. Normal operation achieves a discharge at pH 7.8. Acid addition is set to provide a constant dose which is automatically adjusted to match fluctuations in feed flowrates.

- pH is measured automatically at the discharge, and, if it falls outside the limits of pH 6.5-9.0, then the water is automatically diverted to the emergency surge pond. The pH can be changed by dialing in a new acid dose rate on the acid ratio feed station.

- The sand filters are backflushed every 45 minutes. The filters tend to become sealed by the flocculated metal hydroxides unless the flotation cells are operated at peak efficiency. The sand filter capacity is the main constraint. Backflush is pumped to the equalization pond to be mixed back into the feed flow.

- Lectroclear flotation skimmings are stored in a holding tank. Flocculant Percol 728 (an Allied Colloids Cationic polymer) is added at a rate of 90 ppm ahead of the belt presses. Skimmings are dewatered to about 12% solids on two Parkson-Magnum belt presses. The dewatered cake is conveyed to the feed end of an automatic cement dosing and mixing station.

- 90 lbs. cement are added to each 100 lbs. of skimmings and mixed in a Pettibone Speed Mixer. The apparently dry cake discharge from the belt presses is thixotropic. The cement stabilized sludge drips to a holding point below which it is stored prior to shipment by truck for disposal.

  In 1983 a total of 3,275 tons of fixed sludge was hauled away. During the same period, cement usage amounted to 694,163 lbs. The dry solids content of the skims was 696,000 lbs., the balance was water.

347 tons cement	(11%)
348 tons skims solids	(11%)
2580 tons water	(78%)
3275 tons fixed waste	

WATER TREATMENT PLANT LIMITATIONS

1) The precipitation of manganese plus zinc and Lectroclear microflotation process is accomplished at pH 10.6. To precipitate metals adequately, the pH must be kept between pH 10.2-10.8. It is critical to achieve around 98% or more flotation efficiency in the cells.

2) The Lectroclear flotation step must remove precipitates as efficiently as possible or else the four sand filters clog up.

3) If the acid dosage is incorrectly set, or if a fault arises in the acid dosing system or the pH meters and the discharge pH measures outside the set limits of pH 6.5-9.0, then the water product automatically is diverted to the emergency surge pond to await retreatment.

4) In an emergency, for example, if the sand filters clog and overflow, etc., the building sump gathers spills which are then pumped to the emergency surge pond.

5) Mining operations introduce hydraulic oil into the minewater. Unless it is removed, the reference bulb of the pH probe is likely to become coated and give an erroneous reading leading to faulty operation of the pH adjustment step. An oil boom consisting of floating plastic foam is installed at the overflow from the degrit pond to remove any floating oil film. Hydraulic oil in the water is no problem except when work is in progress underground.

THE ELECTRO COAGULATION CELL

The coagulation cell applies an electric current to the high pH feed solution with lime precipitated suspended precipitates. The process causes flocs to form around small air bubbles.

Up to six amps per gpm of throughput flow are applied in the coagulation cell. This requires currents up to 5000a at the Mount Emmons operation. Depending on conductivity, the higher the amps applied. The more loaded the water, the more amps are generally used.

The coagulant cell consists of a rectangular plan tank with overflow weir at the discharge end. The tank has a V-shaped bottom. The cell is fitted with wire electrodes to which high amperage DC current is applied to the cell which is electrically connected to the flotation basin tank to provide cathodic protection for the steel tank.

Solution flows across a series of horizontal electrodes in the coagulation cell tanks. Exactly how this cell works was not explained by the operating staff. Sketches of the cell showing where it fits in the plant layout, and also of some of the galvanic protection detail, as well as the busbar and electrode arrangement, are provided here.

The power is applied to the electrolytic coagulation cells via a Clinton DC rectifier operated at 28 V and 3000-5000a, the amperage varying with conductivity of the water. Roughly 6a are applied for each gpm of flowrate. The rectifier was supplied by:

CLINTON SUPPLY CO.
Rectifier Manufacturing Division
Chicago, Ill.

The electrodes in the cells are reversed every so often, or the amperage would drop due to a coating that builds up. Approximately every hour, the polarity of the cell is reversed. The electrodes are made of sintered steel by the DURIRON COMPANY. Precise details of the operation and design of the Lectroclear, as well as prices, can be obtained from the supplier:

DRAVO RECOVERY SYSTEMS, INC.
222 Third Street
Neville Island, PA 15225
Telephone: (412) 777-5241
Contact: Ogden Clemens
Robert Merdes

Additional reference to electrocoagulation for metal hydroxide removal has been made by: RAMIREZ & GIANINI (1977), GOTT & LAFFERTY (1977), and RAMADORAI (1978).

LECTROCLEAR FLOTATION

Three Lectroclear flotation basins are installed at Mount Emmons with flow capacities of 500 U.S. gpm, 750 U.S. gpm, and 750 gpm respectively at 750 ppm total suspended solids. The 750 gpm units have a flotation basin capacity of 22,500 U.S. gallons in the bath.

The flowrate and metal concentrations into the water treatment plant at Mount Emmons varies considerably during the year, and the installation of three units was selected so that the smaller unit could be operated for 12 months of the year and the remaining two started up as needed during the 8 months of higher flow.

At the time the plant was installed, Lectroclear flotation in conjunction with electric coagulation cells was the only proven process for removal of the precipitated metals to desired levels. The problem lies in getting the precipitates to coagulate in the very cold water during winter when feed enters the plant very close to 0°C.

More detailed information of the Lectroclear flotation process can be obtained from the vendors, DRAVO RECOVERY SYSTEMS, INC.

The Electrocoagulation and Lectroclear flotation process works well at Mount Emmons. However, it is clear that the units are expensive to install and operate. Electrode life was mentioned as being short enough to add expense. Power requirements amount to somewhere around $150,000/year based on a total power consumption estimate of $180,000 for 1984.

At Mount Emmons, feed to the flotation units runs up to 750 ppm suspended precipitate solids during the low flow season and at these loadings, the flotation units barely remove enough solids to avoid "bombing out" the sand filters. One answer is to dilute the flow with recycle solution to drop the TSS to 400-450 ppm TSS.

To avoid problems with the sand filters at Mount Emmons, the flotation step must work at peak efficiency all the time. The Mount Emmons Lectroclear treated effluent contains 20-30 ppm solids with the discharge from the sand filters at less than 5 ppm.

One of the operating tricks of the Lectroclear cells is to adjust the variable speed skimmer so as to keep the flotation sludge at a density between 2-3%. Outside this range the system performs less well. DRAVO claims that intermittent skimming results in a higher skimmings density up to 3½% solids.

The flotation system works better when flocculant is added as a very dilute solution.

The flotation basins are operated at 25 volts DC maximum, and energy consumption of 3a per gpm is typical.

DRAVO CORPORATION points out that acid mine drainage yields a very gelatinous floc which is more difficult to dewater and dispose of than are precipitated metal hydroxides from plating wastes.

DRAVO claims that the combination of Lectroflotation after Lectro coagulation helps to dewater the floated metal precipitates.

POLYMER SYSTEM

Percol 728 Allied Colloids polymer is delivered to the plant in 50 lb bags. A packaged polymer system is used to make up and age polymer solution.

Percol 728 is supplied by: ALLIED COLLOIDS, INC.
P. O. Box 820
Suffolk, VA 23435

Percol 728 costs $2.25/lb., and annual consumption cost is $10,761.

The polymer makeup plant works well and can take 2 bags of polymer feed per batch. It consists of:

1 Polypak Polymer Feeding System for Adding Dry Polymer to the Mixing Tank
1 Polymer Mixing Tank with Agitator
1 Polymer Aging Tank
1 Milroyal Solution Dosing Pump

Suppliers are:

Milroy solution dosing pump: MILTON ROY COMPANY
1300 E. Mermaid Lane
Philadelphia, PA

Polypak dry Polymer dosing feeder:

BIF - Unit of General Signal Co.
West Warwick, R. I. USA

LIME SYSTEM

Polymer solution is dosed in proportion to flow rate using an automatic addition system which works well at Mount Emmons.

Two lime silos, each with 150,000 lb. capacity, are installed at the site.

These feed two 1000 lbs,/hour lime slakers to make a 6-8% slaked lime slurry.

The lime system was supplied by Wallace & Tierman, Division of Pennwalt Corp.

pH PROBES

Lime addition is automatically controlled by a pH meter and a level probe. A backup system is always maintained on standby:

Great Lakes Instruments Inc.
8855 N. 55th Street
Milwaukee, WI 53223
Telephone: (414) 355-3601

BELT PRESS

The flotation skimmings at 2-3% solids are accumulated in a tank. Percol 728 cationic polymer is added at a dose rate of 90 ppm ahead of the belt press.

Two Parkson Magnum Belt presses are installed. No vacuum is applied to achieve 12% solids in the cake that is discharged.

The Parkson Belt Filter Press is available from:

Parkson Corporation
5601 NE 14th Avenue
P. O. Box 24407
Fort Lauderdale, FL 33307
Telephone: (305) 772-6860
Contact: Michael G. Schill
Sales Manager

Filter cloth lasts over a year, then it starts to tear or fold resulting in a drop in solids level in the cake, or it clogs and doesn't clean up.

The lower media fabric is EE 470.

The upper media fabric is PE 470.

Each media cloth costs $1200.

The Parkson-Magnum presses seem to be doing a reliable job. DRAVO claims now to offer a belt press for this application, too. One problem encountered with acid mine drainage treatment at Mount Emmons is the possibility of sporadic occurrence of hydraulic fluids in the water which saponify at the high pH and could end up blinding the filter press media unless removed.

CEMENT SYSTEM

Cement powder is stored in a 300,000 silo. On demand, the dry powdered cement is fluidized and pneumatically advanced to the cement mixing chamber for mixing with the wet dewatered skimmings.

The purpose of cement stabilization is to make the precipitate easier to handle and to fix the metals. The sludges stabilized in this way were tested and found to meet prevailing leach criteria for landfill disposal.

The pneumatic cement storage and dosing system was designed by Dravo and supplied by:

LUCAS ENGINEERING
Seminole, Florida
Telephone: (800) 237-8989

OPERATORS AND MANPOWER

The Mount Emmons site employs a total crew of six men including the site manager, the water plant supervisor, a night watchman who doubles as relief operator, three plant operators (one of whom takes care of sampling and environmental records) and two additional mechanics, who include electrician and filter skills on a part time or contractual basis.

PLANT CAPACITY

The plant was designed to treat 2200 gpm water. The highest rate at which it has been operated to date is 1750 U.S. gpm. The operators believe it could achieve 2000 U.S. gpm.

The design called for an operating range between 220 and 2000 U.S. gpm.

The Lectroclear flotation plant capacity is limited to the amount of suspended solids that can be removed. The design called for 750, 750, and 550 U.S. gpm flows at 1000 ppm suspended solids achieving a minimum 97% removal of suspended precipitates in the skimmings. After various innovations were developed by AMAX, the units can now achieve 98% removal of solids from the rated flowrate carrying 700 ppm solids.

CURRENT OPERATING LEVEL

At the time of the Randol visit, the plant was treating 75 gpm pondwater and 270 gpm minewater. This was handled by operating the plant two shifts per day.

Mo	ppm	0.01			
Oil	ppm	5			

* Rarely this high

** Detection limit 0.01 ppm Cu

*** Detection Limit 0.0002 ppm Hg

Since startup, the water treatment plant has operated in full compliance with NPDES permit limits.

SCALING

There has been no scale problem at the Mount Emmons plant.

PLANT DESIGN AND CONSTRUCTION

DRAVO ENGINEERING, INC.
Dravo Bldg.
1250 14th Street
Denver, CO 80202
Telex: 45-030
Telephone: (303) 893-4500
Contacts: Terry Amrhein, Sales Manager
Russ Hendrickson,
Project Manager for Mt. Emmons
Augie Clements, Developer of Swift Lectroclear

DRAVO owns the Swift Lectroclear equipment and microflotation process. Dravo also supplies packaged sand filter and coagulation cell packages.

PRECIPITATE DISPOSAL

The precipitated metal hydroxides are skimmed by the Lectroclear flotation process at 1-3% solids. After further dewatering in the filter presses to 12% solids, the cake is mixed with 0.9 lbs. cement per one lb. pressed cake. The cured cement-sludge mix makes the thixotropic sludge both easier to handle and more environmentally stable. The cement stabilized waste meets the EPA leach standards required for landfill disposal.

SAND FILTERS

Four sand filters are installed, and these are used two at a time in series.

The sand filter tanks employed for polishing treated water measure 12' 6" Ø x 17' 4" high. There are four of them. The filters are loaded with sand filter media which was purchased for the initial installation as follows:

171	tons	1-2 mm Graded Silica Filter Media Spherical Mark #4.3
9	tons	1½" x 3/4" Silica Gravel in 100 Lb. Bags
4.5	tons	3/4" x ½" Silica Gravel
17.5	tons	½" x ¼" Silica Gravel
9.0	tons	¼" x 1/8" Silica Gel

So far, since the plant was started up in 1980/81, the sand has not required replacement. Occasionally mudballs are removed from the surface of the filters, however.

Suspended solids in the feed to the sand filters typically run 10 ppm. After polishing in the filters, the suspended solids is reduced typically to less than 1 ppm which is well below that required to meet the suspended solids effluent limit. However, such low levels of suspended solids are needed to meet the limits on total amounts of various metals allowed in the effluents (both dissolved and suspended as a precipitate.)

Compressed air for backflushing the sand filters every 45-minute cycle is supplied by a Sutorbilt Blower made by:

SUTORBILT PRODUCTS
Compton, CA 90224

and fitted with Goddard Silencers.

The sand filters are downflow but fed through an enclosed tank. Two pumps are installed for the backflush cycle.

Ingersol Rand Centrifugal pumps withdraw washdown water and glandwater from a filtered water sump ahead of the discharge point.

GROUNDWATER MONITORING

Groundwater is not monitored at the Mount Emmons Site.

CAPITAL COSTS

The capital cost for the water treatment system including the plant, collection system, and diversion ditch was $10,900,000 in 1976.

According to AMAX, INC., the total capital spent on the site for water management and treatment is close to $14 million.

Some cost items included in this are:

Stabilizing and Covering Keystone Tailings Dams	$ 358,000
Outside Design Engineering	$2,400,000
Plant Building 120' x 200'	$1,706,000
Equipment, Piping for Process and Underground from Discharge Area to Storage Pond, Electric Instrumentation, and Erection	$6,441,000

OPERATING COSTS

Power Costs	$180,000
Labor	$180,000
Supplies	$105,000
Direct Cost Non Supply Items (Sales Tax, Freight, Insurance, Medical Exams, Telephone, Travel, Road Maintenance, Analyses, Etc.)	$260,000
Hauling Waste Sludge	$ 80,000
	$805,000

INTRODUCTION

Disposal of large volumes of wet sludge produced in water and wastewater treatment processes is a serious problem, and is best solved through the use of a dewatering device that will reduce the water content effectively and efficiently.

In general, belt-filter presses are rapidly becoming accepted as effective dewatering devices, due to low energy and maintenance requirements. Also, belt-filter presses operate continuously and do not generally need lime or precoating to assist in the dewatering process. The only limitation of current belt-filter presses is the amount of pressure that can be applied . . . with the result that final sludge cake solids content is not high enough for incineration or economical transportation to a landfill. Parkson offers a new solution to eliminate this limitation . . . the Magnum Press, a belt-filter press with the Third Dimension.

The Magnum Press utilizes a new and unique approach to sludge dewatering in that it provides three functionally separated steps in the dewatering process: draining, low-pressure pressing, and finally a very high-pressure pressing for a sustained period of time (see Figures 1 and 2). The sludge cake produced with this process has a very high dry-solids content (close to that achieved with a plate-filter press) and is of a consistency that allows easy handling and transportation.

© 1977 - Parkson Corporation

Fig. 3 - Schematic view of sludge flow through Magnum Press.

TYPICAL MAGNUM PRESS PERFORMANCE FROM FULL-SCALE DEMONSTRATION UNIT

Application	Cake % Dry Solids	Capture Rate %	Polymer Dose Lbs./Ton Dry Solids
Pulp & Paper			
• Kraft Pulp	27 32	99	4 5
• Sulphite and Mechanical Pulp	30 35	99	7 12
• Fine Grade Printing Papers	45 50	98 99	0.5 1.0
• Tissue	35 40		
Municipal Wastewater			
• Primary and Activated Sludge Anaerobically Digested	30 42	95	4 7
• Primary and Bio Tower Anaerobically Digested	35 40	98	3 6
• Primary and Activated Sludge Aerobically Digested	19 28	98	1/1

How the MAGNUM PRESS works

The press functions in three stages: (1) Draining; (2) Low-Pressure Pressing, and (3) High-Pressure Pressing (see Figure 3 above). A flocculant (usually an organic polyelectrolyte) is added to the sludge before entry into the press, and the mixture is pumped to a flocculator. There, while being mixed, the sludge forms flocs whereby free water is released. This flocculated mixture then flows to the feed box and onto the drainage screen (Stage 1). During transport to the low-pressure section, the majority of free water is drained off. To increase the drainage, the sludge can be subjected to a light pressure provided by rollers and be turned by plows (both optional).

The consistency of the sludge is now such that it can be fed to the low-pressure area (Stage 2) where perforated press rollers of decreasing diameter subject the sludge to continuously increasing pressures. After this careful low-pressure pressing, the sludge is fed into the high-pressure area (Stage 3).

In this last and most important stage the sludge is subjected to very high pressure that is adjustable, depending on the application. This high pressure is generated by a series of 1 inch wide flat belts (see Figure 2) that press the screens against a perforated roller uniformly from side to side. It is this major design advantage that allows the sludge to be subjected to high pressure for a long period of time without producing an excessive load on the screens.

The dewatered sludge is discharged as a pressed sludge cake (see Figure 4).

Fig. 4 - Typical sludge cake from Magnum Press.

PRESSURE/TIME COMPARISON*

*NOTE: AT EQUAL SCREEN TENSION (5KP/CM) AND SCREEN SPEED (1M/MIN.)

Fig. 5 · Graph of pressure/time relationship comparison of Magnum Press and three competitive presses.

The relationship between PRESSURE/TIME and DRY-SOLIDS content

Figure 5 above illustrates the pressure/time relationship of the Parkson Magnum Press as compared to three competitive "high performance" press configurations. Note that the pressure reached in the third stage of the Magnum Press approximates that of a plate-type filter press. Thus, the resulting cakes are almost as high in dryness without the expense and inconvenience of a batch-type dewatering process. It is also important to consider the type of solids and the relationship between pressure/time and resultant dry-solids content. If the pressure is gradually increased, the sludge is effectively dewatered. If the pressure increase is too rapid, the drainage channels by which the water normally leaves the sludge are blocked and dewatering is impaired.

The Magnum Press provides an optimum relationship between pressure/time and resultant dry-solids content (see Figure 6 to the right). Note how the dry-solids content of the sludge increases after each roller, and the dramatic increase in dry-solids content in the Magnum high-pressure Stage 3. The horizontal axis shows the relative time during which the sludge is subjected to pressure.

Fig. 6 · Relationship between dry-solids content and relative pressing time.

INTRODUCTION

There are two particularly interesting aspects of the Waite-Amulet site restoration and maintenance program. First is the HDS efficient treatment plant and secondly the revegetation of high sulfide acidic tailings.

FIG 6. PROPOSED WATER TREATMENT PLANT AT WAITE AMULET
APPROXIMATE SITE ARRANGEMENT

HDS EFFLUENT TREATMENT PLANT

This operation is designed to treat 4320 m^3/d (660 lgpm) acid mine drainage from 8,000,000 tons sulfide tailings on a 100 acre pile and mine drainage from a restored zinc mining site near Noranda Quebec. This plant was designed and constructed after examining all the HDS plants then operating in Canada. Actual construction detail varies somewhat from the proposed layout illustrated below. It therefore represents the best of Canadian experience. Features of the plant that started up in 1984 are:

WATER TREATMENT PERFORMANCE

	Plant Feed	Plant Discharge	Polishing Pond Discharge
pH	2.8	9.7	9.3
Acidity mg/l $CaCO_3$	922.00	0.00	0.00
Alkalinity mg/l $CaCO_3$	0.00	20.00	20.00
Conductivity u MHOS	2740.00	1964.00	2104.00
Cu mg/l	3.1	.02	.01
Zn mg/l	19.2	.02	0.02
Cd mg/l	0.04	LT .005	LT .005
Mn mg/l	5.3	LT .02	LT .02
Fe (total) mg/l	246.00	2.2	0.5
$SO_4^=$ mg/l	1940.00	1050.00	1100.00
Pb mg/l	.05	LT .05	LT .05
Ni mg/l	.06	LT .05	LT .05

- Capital Cost: Estimated C$1.7 million 1983

- Operating Cost (1983 Projection)

Lime	C$231,000	C$0.100 /$m^3$
Polymer	C$ 12,000	C$0.005 /$m^3$
Labor	C$ 55,000	C$0.023 /$m^3$
Power	C$ 32,000	C$0.041 /$m^3$
Total	C$330,000	C$0.142 /$m^3$

- Water treatment costs were significantly cut by reducing the watershed that drains into the affected area from 1000 acres to 313 acres through various diversion projects. Through successful revegetation of the sulfide rich dumps an attempt has been made to reduce the rate of acid and dissolved metal generation.

- Being located in a cold climate, the Waite Amulet treatment plant including thickeners is installed indoors in a 2730 ft^2 building measuring 42' wide x 65' long x 34'.

- To accomplish the compact plant a lamella platepack thickener is used inside a small indoor clarifier tank.

Liquid Polymer Metering Pump
Note Aging Coil in Rear

Innovative Lime Addition Line
Can be moved from one tank to another very easily.

FIG 8. PROPOSED WAITE AMULET WATER TREATMENT PLANT BUILDING
GENERAL ARRANGEMENT TOP FLOOR

FIG 9 PROPOSED WAITE AMULET WATER TREATMENT PLANT BUILDING

GENERAL ARRANGEMENT - ELEVATION VIEW

- The Waite-Amulet system includes:

  - Acidic water retention pond - adequate for one in 25 year rainfall containment. 242 acre-feet.
  - Water treatment plant for 660 lgpm allowing 20% margin over the required one in ten year maximum flow rate of water needing treatment.
  - Polishing pond for treated effluent
  - Three division sludge storage and dewatering ponds with porous sand floors.
  - Provision to add lime at the decant point to any excess effluent over and above the capacity of the treatment plant that might have to be released in an emergency to Lake Default.

- The HDS plant consists of the following:

  - Lime storage. 60 ton skirt supported outdoor lime silo.
  - Lime slurry preparation system 1/3 HP Lightnin mixer, 3-4 minute retention, deep vortex mixing, Schutte & Koerting water jet eductor, lime slurry pump.
  - Lime-recycle sludge mixing tank. Prochem 10HP mixer.
  - Two neutralization reactors each 15,200 l gallons mixed by Prochem agitators with baffles and air lances at 7 psi.
  - One 26'Ø X 20', 60,000 l gal. thickener fitted with an Axel Johnson LGS-T3200-55 Lamella Plate Pack. The thickener has a rake mechanism to bring sludge to a central discharge point.
  - 12'Ø X 15'6" h. sludge storage tank, 10,400 l gal.
  - 400 cfm blower system 15 psi.

- The HDS plant at Waite-Amulet was required to reduce the volume of precipitate sludges generated. A 3.3 active acre lagoon would have been adequate storage for only 3-6 months sludge generated by conventional neutralization.

- Preliminary test work was conducted by P. W. Shipley of P. W. Shipley Associates.

- Cost of lime at the Noranda, Quebec site is $144/st in bulk. Lime demand in 1984 was 12 lbs per 1000 l gallon or 1.2 Kg lime/m^3.

- The Waite-Amulet HDS plant is designed to be completely automatic. Controls and sensors place the plant on hold when there is a shutdown and signal a problem at at the Horne Division Control Room.

- The plant is operated at a steady flow of 800 lgpm provided by a pump at the pond. This steady flow feature is one of the keys to trouble-free operation. When there is inadequate water in the pond to achieve this flowrate, the plant shuts itself off.

- Flowrate is measured using an ultrasonic device on a Parshall flume, which measures flow and solids density of the underflow, made by:

  Marig, Inc.
  #230, 3300 Boulevard Cavendish
  Montreal, Quebec H4B 2M8

  Telephone: (514) 487-1024
  Telex: 055-66305

- For the automated plant, hydrated lime was selected over quicklime to avoid the need for a slaker or storage reservoir and to minimize operator and maintenance requirements. At the time of the visit NORANDA had not yet reached a final conclusion on the relative merits of quicklime vs. hydrated lime.

- Lime discharge from the feeder is connected to a totally enclosed polyethylene mixing tank. Makeup water is piped through the lid of the tank at a constant flow rate to produce 30% slurry at maximum lime demand of 20 lbs/minute. The water nozzle is positioned to induce a deep vortex in conjunction with a 1/3 HP Greey-Lightnin mixer. Lime flowing into the vortex is carried to the downdraft impeller where it mixes instantaneously to produce a lime slurry. The mixing tank has a 3-4 minute retention time providing a fast response to the control loop.

- A submerged overflow from the lime mixing tank flows into an enclosed funnel which discharges to the suction port of a "Schutte and Koerting" type 264 carbon steel water jet eductor. Even though a 1½" water jet eductor can handle 5/16" particles, the submerged overflow at the mixing tank prevents any non-dissolved lime from reporting to the eductor. The system requires only 21 gpm at 60 psi to carry 8 gpm of 30% lime slurry against 15 psi back pressure. The system has proven itself to be simple and reliable to convey a lime slurry for the short distance with only 22 ft lift to the reactors.

  By enclosing the rotary feeder discharge the lime mixing tank and the eductor funnel, and by operating the eductor so that the air is drawn from inside the sytem, a slight negative pressure is created in the lime system and the escape of lime dust is minimal. This system is installed at both Geco Division and Waite-Amulet with successful results.

- <u>Sludge-Lime Mixing</u>

  Sludge is recycled to the lime-slurry mixer fitted with a Prochem 10 HP Type 640 ft/s agitator at 44.6 RPM. The baffled sludge recycle tank measures 12'Ø x 6' high with 3200 lgal. (14.5m³) storage capacity, designed for 15 minutes retention. This modifies the sludge solids from a fluffy slime to an almost particulate texture.

- Neutralization Reactor Tanks

  Two reactors each 15,200 I gallons (69 m^3 each) are sized for 23 minutes residence time not counting sludge recycle and 20 minutes including sludge recyle, indicating 27.3 m^3/h sludge recycle.

  The tanks are of mild steel with mixing and discharge baffles and a cone bottom discharge. All wetted parts are coal-tar-epoxy coated. One Prochem agitator is installed in each tank.

- In the original design air was to be injected in the primary neutralization reactor at 15 psi and 400 scfm (0.6 scfm/Igpm) to convert ferrous to ferric. The idea was to minimize gypsum scaling by keeping an accelerated motion of the particles while they formed.

  In the operating plant, however, air was injected at 7 psi via four removable air lines per tank inserted to below the Prochem mixers.

  To prevent spillage, and to contain any foam that might occur, the tanks are provided with 2.5' freeboard which makes an obvious difference to the cleaniness of the plant.

Polymer System

Liquid polymer is used which is much simpler to use than a dry polymer makeup system. Liquid polymer systems are currently in use at two INCO plants and at NORANDA MINES LTD. GECO DIVISION.

Alchem HC35 flocculant was in use at the time of the visit, although Alchem 8C26, 8C35 and 87079 had been tested.

In the original design, liquid polymer was to be introduced via a variable speed "Liquid Metronic" model D73 pump. However, a Stanco Polyblend Bradley Illinois polymer pump was installed. The flocculant is mixed into thickener o/f water bleedstream via a T static mixer and then passes through a 300' clear plasic 1"Ø pipe acting as an aging coil before being injected into a 5gpm stream for a second dilution which carries it to the delivery point which is achieved by inserting the end of the diluted flocculant solution delivery line into the overflow upcomer at the discharge of the second neutralizing tank allowing flocculant to disperse in the water as it cascades down the trough leading to the clarifier.

The use of flash mixers for flocculant mixing was dispensed with after Noranda staff visited several installations where the static mixers or propeller mixers had been removed.

Solid/Liquid Separation

Noranda measured clarification rates for hydroxide thickeners at 0.2 - 0.5 lgpm/ft^2 (0.54-1.36 m/h). To enable the clarifier to operate indoors a lamella clarifier was selected. Conventional thickeners operated in Canada experience interference due to surface currents on the sludge blanket. A circular thickener 26 ft Ø x 20' high walls sides is installed and fitted with an Axel-Johnson LGS-T3200-55 Lamella plate pack and a rake mechanism to bring sludge to the central discharge point.

Sludge level is detected using a Sensall device supplied by:

National Sonics Division
Sensall Control
Xertex Corporation
Hauppauge, NY 11787

The Lamella plate packs are made by:

Axel-Johnson Ltd.
Montreal

Clarifier overflow is pumped via a Sclairpipe line to a 2.5 acre polishing pond which overflows to the creek system at pH 8.5-9.5.

Sludge Handling

Based on experience at Noranda Mattabi Division where the original Moyno pump was replaced by a SRL type centrifugal pump, the latter was installed at Waite-Amulet. Positive displacement pumps normally prefered for this job require so much maintenance that the benefits do not offset the greater reliability of SRL centrifugal pumps. Flocc breakage can be overcome by a little extra flocculant dosage.

At Cominco's Kimberly BC plant two SRL Allis Chalmers pumps are installed, each capable of recycling 850 lgpm sludge. At Kimberly the pumps are fitted with DC variable speed motors, and one pump operates at a time. Cominco reportedly initially experienced problems with constantly changing polymer dosage requirements created by the solid mass flow not being uniform. The RPM of the motor is now controlled to draw a constant amperage. In this way a change in sludge viscosity or density caused by a sudden slide of material to the thickener discharge cone is taken care of by a change in pump rpm.

To achieve 25-30% sludge density, 95-98% of the sludge must be recycled. At Waite-Amulet two Worthington 3" X 3" horizontal rubber lined slurry pumps were installed as slurry recycle and sludge waste pumps. One heavy duty AC motor and a single controller were selected for the variable speed sludge recycle pumps.

The sludge recycle pump and sludge waste pump are located in a pit under the thickener which minimized the length of the suction line to the pumps. One Galligher sump pump acts as a backup for either the recycle or waste sludge pump. The sump is designed to discharge its overflow to the clear water overflow ditch.

Recycle flow monitoring is by a Taylor mag-pipe flowmeter installed on the sludge recycle line. The purpose of the sludge flow measurement is to be able to optimise the flocculant/recycle ratios and to shut the plant down automatically if the recycle sludge volume drops below a preset limit.

Sludge Disposal

Once sludge density has been reached the sludge waste pump is activated for a timed period by an ultrasonic sludge level detector supplied by National Sonics Division, Happauge, NY (address given above.)

To minimize the amount of spare parts, this pump is identical to the recycle pump but with a standard AC motor which is feasible because the sludge pond is only 300-400 ft from the treatment plant and at the same elevation.

The sludge disposal line is insulated and has a 1½% slope back to the treatment plant. After every sludge purge the line is be flushed. The waste pump header is connected to the upper part of the clarifier and by means of automated knife valves, some of the clear water will be used for the flushing of the line by the waste pump. After the flushing sequence has been completed an automated knife dump valve will be activated to drain the line.

Sludge production is estimated at 2.6 acre-ft/year and a 10 acre-ft sludge disposal pond has been constructed adjacent to the plant.

The sludge impoundment system has a porous base of sand and cobble to drain the sludge to 50% solids.

The sludge pond consists of sand beds fitted with buried pebble size slag drains. The impoundment is divided into three sections which are cycled to provide maximum drying before being covered with fresh material.

During winter dewatering is limited but as the spring thaw arrives the drainage characteristics of the once frozen material is greatly enhanced. In summer drying will remove additional moisture causing shrinking and cracking which allows air to come into contact with the sludge. There will be some conversion from ferric hydroxide to the carbonate too. This results in a very stable dry sludge. It was still too early to determine whether metals leach from this sludge although it is considered highly unlikely.

A similar sludge leach tested by Cominco at Kimberly BC was said to have resulted in virtually no dissolution of heavy metals but more information on this could be requested from:

Mr. Walter Kuit
Cominco Ltd.
200 Granville Street
Vancouver, BC
V6C-2R2

Telephone: (604) 682-0611

At Waite-Amulet, the storage ponds are about 300 ft x 500 ft long divided into three sections with clay dikes with a usable storage height of 5 ft.

Dry sludge production rate is estimated at 4000 tpa or 2.6 acre-ft/year. Utimately dry sludge will be hauled to one of the tailing sites for final disposal.

Drainage lines from the sludge impoundment exit to a drain for gravity flow to the acid feed water reservoir. In future this water could be diverted to the clear overflow ditch once its good quality has been confirmed.

Control System

A very innovative automatic control system has been installed at the Waite-Amulet water treatment plant. The heart of the system is a programable Texas Instruments micro-processor which is equipped to handle on/off analogue input/output as well as timing, counting and arithmetic functions. The input/output configurations are simple and easily traceable in the event of malfunction or logic error.

The micro-processor has three prime functions:

- generating temporary shutdown on critical alarm
- monitoring and recording of plant operation
- restarting the plant after power failure

The plant is also wired for manual operation at the central control panel although it is intended to be operated as a remote unmanned automatic unit except when the unit is being worked on or optimized.

The microprocessor is programmed to handle signals from a variety of contact switches associated with field instruments:

- High pH at neutralization tank #1
- Polymer delivery line pressure
- High sludge bed level
- High efficient turbidity
- High clarifier rake torque 70% of maximum rated torque
- Medium high clarifier rake torque at 40% of maximum rated torque
- Low pH in neutralization tank #1
- Low water supply pressure
- Low compressed air pressure
- Low raw water pond level
- Low sludge recycle flow

A Leeds & Northrup 5 channel recorder continuously records the following parameters:

- Turbidity of Overflow
- pH of Reactor Tank #1
- pH of Reactor Tank #2
- Inlet Flowrate
- Sludge discharge Flowrate

Services

The water treatment plant facility operates at 150 HP installed power and 75 KW for heating at the coldest period. Cost of installing a 25KV line for the installation was $55,000.

The microprocessor is connected by telephone line to the Horne Division to continuously transmit plant operating status and for communications with the plant operator.

The plant also needs 60 Igpm fresh water to operate. This is supplied by installation of one two stage Flygt pump alongside the Duprat River about 1500 ft from the plant to provide fresh water for polymer preparation, lime slurry preparation and transport, pump glands and for floor washing.

TAILINGS AND SITE REVEGETATION

The Waite-Amulet tailings are one of the very few high sulfide tailings which to date have have successfully been revegetated with a self-sustaining cover.

The 7-8 million ton No. 2 dam tailings consist of 50-60% pyrite (60% - 325#) and a smaller swampy pond area were active acid generators. Samples of water from the seepage collection ditch run pH 2.8.

Mine water drains from the old underground workings at around pH 7.2-7.4, and the only deleterious contaminant is iron. This water is divereted in an open ditch around the tailings area and by the time it is discharged to Duprat Creek, it meets discharge limits.

There are two tailing dumps known as the No. 1 and No. 2 dams. Of these, the No. 2 dam is by far the largest.

An important aspect of restoration of the mine and tailings site has been the diversion of water from several watersheds that used to drain into the tailings area.

The No. 1 tailings dam which was was laid down prior to 1929 has been clay covered and revegetated. There are one or two acid springs in the vicinity from which water at pH 2.9 is emitted, but the cause or source of this water is not known.

The No. 2 sulfide tailings dam has been successfully revegetated with birdsfoot trefoil, a nitrogenous legume after spreading 25-40 tons per acre lime and one ton per acre fertilizer over the surface of the material. The tailings were, however, not capped by a clay layer.

The tailings revegetation program for Waite-Amulet was initially started under the direction of W.J. (Bill) Marshall, a Noranda Environmental Coordinator who has subsequently retired.

BIOASSAY TECHNIQUE

During the past decade of research, trial, and error, the Horne Division of Noranda, which is responsible for the Waite-Amulet site, has developed a concept that is unique in the field of reclamation of sulfide tailings. This concept involves using bioassay techniques to determine the vegetation potential of the wastes to find out whether and what species can be directly seeded, and developed into a maintenance free plant cover. The aim is to find a way of direct seeding of sulfide waste without the need for overburden cover, capillary barriers, or additional topsoil covers.

A two year university investigation by the University of Guelph proved that chemical soil analyses are unsuitable as a means of developing a reliable field reclamation program.

The bioassay technique reveals any wide differences within and between sites as far as dosages of agricultural limestone and fertilizer needed to sustain plant growth. It also indicates where an overburden application is necessary.

ORIGINAL REVEGETATION PROGRAM

The first attempt by Noranda to revegetate the Waite-Amulet tailings disposal area was undertaken in 1969. A reclamation contractor with experience in this field gave Noranda a written guarantee before discing the stable primary tailings area and applying lime, 650 lbs.t 10-10-10 fertilizer, and seeding with 256 lbs/acre of perennial rye and New Zealand Fescue grasses. This approach, which had worked in the Sudbury basin and at Timmins was a complete failure on Waite-Amulet tailings.

Even after applying 7 tons lime per acre to the tailings in a second attempt, the results of a second seeding were a complete failure.

Noranda commenced a test program in 1972 to find a way to revegetate the Waite-Amulet tailings. Bottle tests of tailings material indicated that 25 tons lime would be needed to sustain a pH that would support plant growth. The 1972 test plot program using 50 tons lime/acre, and 1200 lbs/acre of 5-20-20 fertilizer with a seed mixture of equal proportions of birdsfoot trefoil, Canada bluegrass, Timothy, Red Top, and creeping Red Fescue with 100 lbs/acre of a nurse crop of barley or oats in some cases demonstrated that vegetation could be grown on high sulfide tailings, but at a high cost.

UNIVERSITY OF GUELPH - CHEMICAL ANALYSIS

In 1974, a 5-year research program was started between Noranda and the University of Guelph, one of the foremost agricultural research centers in North America. Two principal aspects were investigated:

a) To determine the degree of variation within and between high sulfide tailings and its effect on plant growth.

b) To improve or develop techniques to establish permanent vegetation cover on high sulfide tailings.

None of the many analyses revealed any consistent relationship between the various parameters. Analyses for total and water soluble components, relationships between sulfur and sulfate in non-oxidized and oxidized tailings and for iron, heavy metals and sulfur concentrations all provided inconclusive.

Although attempts to predict vegetation supporting ability from chemical composition data proved futile, the use of empirical practical growth experiments in a growth room under different additive conditions proved to be useful.

Using the growth room, results that might require three or four years work in the field can be obtained in four to six months. Growth room investigations were performed through the winter months.

The growth room tests were tested in the field in 1975 and experiments were undertaken to find more economical pH modifiers than limestone. Anhydrous ammonia raised the pH from 3.4 to 7.2 instantaneously but the seeds failed to germinate. Fly ash proved an excellent pH amelioration material but transportation costs were prohibitive.

Noranda-Guelph next undertook a comprehensive evaluation of the entire Waite-Amulet tailings in the growth room using the biossay technique developed in the previous 5 year program. Over twenty samples of Waite-Amulet tailings were obtained for the study and these represented a wide range of variations in color, granulometry, location and surface moisture content. The tests proved that although a single fertilizer application rate was suitable for the entire dam, limestone requirements varied from 10 to 75 tons/acre. Surface plans were developed to indicate contours for limestone rates to be applied at various areas of the dam.

As Noranda's knowledge of the Waite-Amulet area increased, so did its awareness of the fact that reclamation of a tailings area was just one facet of a complete ecological program.

A schedule for application of agricultural limestone, fertilizer, and seed was started in the fall of 1978 when the tailings surface was dry enough to allow large agricultural equipment to operate, but before the surface moisture had evaporated due to the extremes of summer heat and the tailings texture and color. It was known that contrary to popular belief, photosynthesis of plants is not continuous while the sun is shining. Photosynthesis may almost completely stop at the height of summer heat. Light colored tailings reflect excessive radiation to the plant surfaces and intensify physiological stress. INCO has measured under leaf temperatures as high as 140°F.

WAITE-AMULET REVEGETION TECHNIQUE

The technique used to revegetate the Waite-Amulet dam followed the following procedure:

1) Where a hardened crust or hard-pan had formed as a result of oxidation of the tailings, the surface was ripped or disced depending on the thickness of the hardpan.

2) Agricultural limestone was applied using a rotary spreader on a 10 ton capacity wagon.

3) An 18-foot rotovator was passed over the area which resulted in a well mixed and level seed bed.

4) Next, fertilizer was spread using a standard box fertilizer spreader. The Waite-Amulet required a blend of 1,500 pounds of 5-20-20 and 500 pounds of 0-46-0 fertilizer per acre. Fertilizer without filler material was used to reduce shipping costs.

5) Fertilizer was incorporated using the adjustable teeth of a culti-packer. The machine also compacts the tailings to form a firm seed bed. A harrow was attached to the culti-packer to prepare the seed bed for mechanical seeding--it is not needed for hydroseeding.

6) The area was then seeded using:

   a) A split-box Brillion seeder on areas which were relatively flat and able to retain some surface moisture.

   b) A hydroseeder on areas which would not retain adequate moisture, which were prone to wind disturbance, or which were crested or sloped. A Canadian-made straw and cotton waste mulch was applied at 1400 lbs/acre to all areas which were hydro-seeded.

7) Two seed mixtures were used:

a) For wet, fine-grained areas:
30 lbs per acre of tall fescue (K31)
20 lbs per acre birdsfoot Trefoil.

b) For relatively dry, coarser grained areas:
30 lbs per acre creeping red fescue
20 lbs per acre birdsfoot Trefoil.

Excellent results were obtained with 90% coverage after the initial growing seasons. More than 6 years later in 1984, the area continues to support a lush growth up to three feet high which requires no additional care or maintenance.

The smaller secondary tailings dam at the Waite-Amulet property is located in a low-lying swampy area which is unsuitable for heavy farm equipment. This area was reclaimed by placing a clay capping over the tailings and surrounding swamp prior to seeding. This could only be done during the winter months. The cost of this technique is four to five times higher than direct seeding.

All major fresh water streams running through the swampy tailings area were diverted prior to placing the clay cover over the area. The largest creek was ditched to a new receiving stream almost a mile to the north while a smaller tributary was piped through the area in an 18-inch polyethylene pipe.

CONCLUSIONS

Noranda's efforts to establish vegetation on highly acidic mine tailings and swamps have been successful so far. The ability to establish maintenance-free vegetation cover on acidic mine tailings has been demonstrated.

The bioassay method using growth rooms has provided a new and useful method of selecting appropriate soil conditioning and seed mixes for a given site.

At Waite-Amulet a successful self-sustaining vegetation cover consisting largely of birdsfoot trefoil was established, but this is being successfully invaded by indigenous species as evidenced by the appearance of many trees on the Waite-Amulet site. Many of these trees were over 15 feet in height by 1984, and a florishing wildlife habitat has been established over the area.

The dense vegetation cover over tailings achieves the following:

1) Vegetation appears to have reduced the volume of acid seepage from the dam. Vegetation utilizes very large quantities of water in its life processes and loss through transpiration. The plants intercept much of the precipitation which evaporates into the atmosphere before reaching the acidic tailing surface.

2) Dense vegetation has eliminated the previous serious dusting problem.

3) The aesthetics of the area have been greatly improved. Organic matter from seasonal plant decay and growth has developed into a soil layer.

4) Noranda is still evaluating whether or not vegetation has an effect on the quality of seepage water from the area. Noranda has concluded that revegetation is just one part of a multi-faceted program in restoration of abandoned minesites.

An important aspect of the successful Noranda project is that a capillary barrier is not always necessary between vegetation and high sulfide tailings.

Consultants and service companies that were involved with Noranda in this successful project include the following:

Noranda has undertaken several additional experiments in an effort to find better ways to restore mine tailing sites. In one of these a lazer-controlled subsoil plough was tested to lay slotted pipes in the tailings in an attempt to drain them. This type of subsoil plough is used by drainage contractors and is offered by a company known as Big-O (Canada) Ltd. Slotted pipe installed into a test area in 1979 is still producing water in 1984. More information on this test is available from:

Professor Bob Broughton
Department of Hydrology
McGill University
Montreal, Quebec

The area around the water treatment plant at Waite-Amulet and all earthworks were seeded to provide a grass cover using a hydroseed mulcher at a cost of C$1100/acre.

In Canada there is more than one revegetation contractor who offers patented mulch mixes.

A good review paper on revegetation of sulfide tailings ponds is provided by WATKIN & WATKIN (1982), Tailings Reclamation in Eastern Canada, World Mining, December 1982.

ULTRASONIC FLOW METERS

Monitoring of liquid flows in open channels can be accomplished reliably and economically through the use of the MARIG series of ultrasonic flow meters. Each meter is completely solid state, microprocessor based, and pre-calibrated for a wide range of flumes and weirs.

Field selection of alternate primary elements is provided through two BCD switches. Totalizing, flow and range are also BCD adjustable. Solid state temperature compensation is available with an accuracy of 0.1%.

FLOW MEASUREMENT

FLUMES — PARSHAL / PALMER-BOWLUS / LEOPOLD-LAGCO
WEIRS — RECTANGULAR / V-NOTCH / CIPPOLLETI

LEVEL MEASUREMENT

RESERVOIRS / TANKS / BINS / PUMPING STATION CONTROLLERS

SPECIFICATIONS:

Repeatability	0.1%	Minimum Range	18"
Linearity	0.1%	Maximum Range	12'
Accuracy	1 %	(Dependent upon flow)	

Temperature — Electronics −20° to +50°C
— Transducer −40° to +70°C
Approximate weight 20 lbs.

FEATURES:

- Flow totalizer
- Sampler relay
- Instantaneous flow rate indicator
- Strip chart recorder (F.I.R.-100)
- Programmed flow curves
- NEMA 4 plastic enclosures c/w clear covers are standard for Model F.I.R.-100
- NEMA 12 enclosures are standard for Models F.I.T.-50A and F.I.T.-50D
- 6 digit totalizer totals in 100, 1,000 or 10,000 unit increments
- Sample rate adjustable. Samples every 1 to 99 units of totalization
- 0-1 mA output for analog meter (50A)
- 0-10 V. output
- 4-20 mA output (ground referenced, into 750 ohm max. load)
- Echo loss indication
- Temperature compensation - compensates for temperature change at the sensor.
- Standard cable length 20'

TRANSDUCER:

Barium titanate element in C.P.V.C. outer housing. (optional: 316 SS)

MODELS:

F.I.R.-100

- Flowrate Indication (digital)
- Flow Totalizer
- Strip Chart Recorder
- Sampler Relay
- Programmed Flow Curves

SLUDGE DEPTH METER

MARKLAND MODEL 600

FEATURES

- SOLID—STATE (NO MOVING PARTS)
- INTELLIGENT MICROPROCESSOR INSTRUMENT
- VERY HIGH INTENSITY L.E.D. INFRARED BEAMS
- AUTOMATIC INTENSITY CONTROL
- COMPUTER COMPATIBLE
- 4-20 ma OUTPUT LINEAR WITH SLUDGE DEPTH
- HIGH & LOW SLUDGE DEPTH SET-POINT RELAYS
- PROBE 'TIP-UP' SWITCH
- SELF-DIAGNOSTIC

MICROPROCESSOR CONTROL

A microprocessor scans the Probe elements and locates the sludge bed if there is one, and displays this on the L.C.D. Any bottom offset is automatically incorporated into the reading. Out of range, or zero readings are displayed if there is no sludge/liquid interface. Error trap routines identify and reject bad scans. To lessen the impact of short term events such as passing 'clouds', the Meter accumulates a running-average of several good scans, which dampens the response and smooths the output. If after several attempts, the Meter can not obtain good scan data (i.e. broken wire, etc.) the L.C.D. reads "SIGNAL LOST", both Relays are de-energized, and the 4-20 ma output goes to zero indicating *fault*. During a fault condition the Meter continues trying to find good scans and resumes normal operation as soon as good data is obtained. Using techniques borrowed from computer photographic enhancement, the microprocessor disregards individual beam signals which are not consistent with those on either side; thus, spot fouling, or floating clumps are ignored, and minor failure in Probe elements merely creates a 'dead spot'. The entire Probe does not have to be replaced. Automatic intensity control adjusts the L.E.D. firing power to the correct level for each particular sludge/liquid. Progressive slime buildup on the Probe merely results in the instrument boosting its own power to the intensity required to shoot through the scum. An integral self-diagnostic routine displays the Microprocessor's memory on the L.C.D., and makes troubleshooting easy.

PROCESS CONTROL

A desludging pump can be operated automatically from the Low Set-Point along with a Pump Run-Interval Timer, and the High Set-Point used as an alarm for excessive sludge depth. Alternatively, the desludge pump can be turned ON at the High Set-Point, and OFF at the Low Set-Point. The Meter is useful for decant control, resin level monitoring, and slurry inventory assessment. Online real-time computer monitoring of sludge depths is accomplished through the 4-20 ma output.

OTHER MARKLAND SYSTEMS

Markland's portable sludge level detector, the SLUDGE GUN®, is a valuable operating tool for manual sludge bed detection. Markland also manufactures ultrasonic Meters for controlling sludge levels or monitoring suspended solids. Markland DUCKBILL® wastewater Samplers operate without mechanical moving parts for reduced maintenance and high reliability. Write for a complete catalog of Markland products.

SPECIFICATIONS

Materials	Probe — PVC Mast — PVC Pipe Clamp — Stainless Steel & Polypropylene Cable — Vinyl Jacketed Enclosure — Fiberglass Body & Clear Plastic Cover
Dimensions	Probe: Overall Length 1330 mm (52¼ in.) Active Element Length 1219 mm (48 in.) Cross Section 64 mm (2½ in.) x 38 mm (1½ in.) Gap — 25 mm (1 in.) Mast — 3½ metres (12 ft.), 1 in. Sch. 80, shipped in 3 pieces with fittings Cable: Probe Pigtail — 10 metres (33 ft.) Enclosure: Width 350 mm (13¾ in.) • Height 350 mm (13¾ in.) • Depth 200 mm (7⅞ in.)
Cable Length	10 metres (33 ft.) pigtail supplied (measured from top of Probe). Maximum cable length 150 metres (500 ft.). Order extra cable separately if pigtail length not sufficient.
Active Element Spacing	64 pairs infrared L.E.D./Phototransistor, spaced vertically on 19 mm (¾ in.) centers
Accuracy	± 2 cm (± 1 in.)
Bottom Offset	Switch adjustable, 0 - 99 cm, or, 0 - 99 in. (Note: For Model 600-DAF, this is TOP OFFSET)
Depth Units	Switch selectable, inches or centimeters
Temperature	Maximum 50° C (120° F)
Power	120 volts, 60 Hz, or, 220 volts, 50 Hz, 15 watts
Outputs	• Liquid Crystal Display (L.C.D.), 16-Digit Alphanumeric • 4 - 20 ma output signal, linear with sludge depth • Two DPDT, 5 Amp. Relays, independently adjustable set-points
Response Time	30 seconds
Microprocessor	6809 with one EPROM and one EEPROM

INTRODUCTION

Rooiberg operates three mines in the northern Transvaal between Warmbaths and Thabazimbi in an area which is short of water. The available underground water in this area is also high in fluorides and the available minewater contains 6-10 ppm F^- which is considered to be detrimental to healthy teeth formation in growing children.

Of interest at Rooiberg is the new fluoride removal process that has been designed based on tests by the NIWR (National Institute for Water Research) in Pretoria, and which uses activated alumina to remove fluoride. Two identical processes have been installed, one at the A mine and another at the C mine. The plants produce 500 m^3/d of drinking qualtiy water which contains less than 1.5 mg/l of fluoride in the product water.

MINE LOCATION There are three mines in the Warmbaths, Transvaal area:

- A Mine
- C Mine
- Vellefontein Mine

A and C Mines are 21 km apart.

WATER SUPPLY

A Mine has an irregular water supply and has often been short of water.
C Mine has adequate fissure water available, which contains 6 to 10 mg/l of fluoride.

In order to supply water to A Mine, water is pumped from C Mine by pipeline. Several tapping points along the line provide water to farmers for livestock. The pipeline was installed by late 1982, it is a 10" (250 mm) line which cost R1.0 million.

A Mine has some boreholes which do not yield an adequate supply.

WATER CONSUMPTION

At the Rooiberg operation net consumption of water by the mine community works out to 0.8 m^3/person/day which is considered higher than average in South Africa. Water consumption by the flotation plant was not obtained, although water is reclaimed for reuse from the tailings dam.

WATER QUALITY

Minewater from fissures in C mine contains 6-10 ppm F^-. This fluoride level is detrimental for growing children, especially in early growth stages during tooth development even though a seriously impacted health case was never found in the area. World Health standard for F^- is 1 ppm in drinking water.

A study investigated the possibility of distributing defluoridation systems to each household so that only potable water would be treated. Eventually it was found more practical to install a central plant. The CSIR conducted a literature search on the subject of fluoride removal.

The minewater is also relatively high in dissolved silica (12-14 ppm) and has 30-70 ppm NO_3 contributed by explosives used in the mine and small amounts of Cu, Sr, Ba, Fe and Mn.

FLUORIDE REMOVAL PROCESS

The process selected for defluoridation of Rooiberg water is adsorption onto activated alumina. When the F^- adsorption capacity of the alumina bed is exhausted; i.e., when the product water contains 1.5 mg/l of F^-, the alumina is reactivated with 1% NaOH solution. After reusing and neutralization with dilute H_2SO_4 the full adsorption capacity is restored.

A regeneration cycle effluent containing high fluoride and salt levels is to be disposed of by using it as a vehicle to pump tailings onto the tailings dam.

It was mentioned that the actual plant will be much more conservatively designed than the parameters supplied by NIWR which are shown in the data and diagram presented here.

CAPITAL COST Plant plus Reticulation System R0.75 million
Includes Reticulation System
Two Plants, One at A Mine, one at C Mine

PLANT SIZE 518 m^3/d for each plant

OPERATING COST R0.33/m^3 treated US \$0.20/m^3

PROCESS SELECTION

The CSIR carried out a literature search and found several approaches to fluoride removal from water.

- Reverse Osmosis Works well and gets F^- down lower than needed. Costs 50% more than alumina process. Fouling by Cu, Sr, Ba, Fe, Mn and membranes need weekly citric acid cleaning. Estimated R. O. cost R0.55/m^3.

- Chemical Addition
  - Lime addition - cannot achieve below 8 mg F/l.
  - With additional $MgSO_4$ and alum can achieve below 1.5 ppm F^-, by coagulation and flocculation but requires costly reagents and sludge disposal.

- Ion Exchange
  - Several ion exchange processes are employed including activated carbon, strong base ion exchange resins, bone char, tricalcium phosphate and activated alumina.

A disadvantage of activated carbon is that it works best at pH 3 which would require too much reagent also for raising pH of product water again.

Advantages of Activated Alumina:

1) Activated alumina is very specific.
2) Has a high capacity for F^-. In South African tests 3.2 F^-/l of Settled Al_2O_3 was achieved. 5 g F/l under special conditions is achieved in the USA.

3) Al_2O_3 is not friable, attrition losses are low.
4) Al_2O_3 is not affected much by Cl^- and $SO_4^=$.
5) Regeneration is simple using NaOH.

Based on the above, the activated alumina process was selected.

FLUORIDE REMOVAL PROCESS

The process and design criteria are described in the following information sheet provided by the CSIR National Institute for Water Research.

March 1983

Fluoride removal from drinking-water by activated alumina adsorption

INTRODUCTION

Fluoride in drinking-water may be beneficial or detrimental to health (particularly of infants and young children), depending on its concentration. In excess of 1,5 to 2,0 mg/ℓ fluoride is known to cause permanent grey or black mottling of tooth enamel and the longterm intake of 3 to 10 mg/ℓ may result in abnormal bone growth in both humans and animals[1,2,3]. On the other hand a fluoride level of about 1 mg/ℓ has been shown to reduce dental cavities in children significantly[1,2], and this concentration level is widely recommended for the growth and maintenance of strong, healthy teeth.

Many groundwaters in the Republic of South Africa are unfit for human consumption because they contain more than the maximum allowable limit of 1,5 mg/ℓ fluoride recommended by the S.A. Bureau of Standards. Fluoride concentrations in groundwater vary from about 2 to 20 mg/ℓ, with levels up to 10 mg/ℓ being fairly prevalent.

DEFLUORIDATION METHODS

Fluoride removal methods can be divided into two categories - those based on the addition of chemicals to cause precipitation or co-precipitation during coagulation and those based on ion exchange or adsorption.

Chemical addition includes the use of lime and magnesium and aluminium salts. Theoretically, lime can reduce fluoride to no lower than 8 mg/ℓ, while fluoride levels of less than 1,5 mg/ℓ can be attained using aluminium and magnesium sulphate. However, excessive and therefore costly dosages are required to remove small amounts of fluoride and the resultant sludge disposal problem makes chemical addition unattractive.

Adsorbents that have been evaluated include activated carbon, strong base anion exchange resins, bone char, tricalcium phosphate and activated alumina[3,4,5,6].

Of these adsorbents, activated alumina appears the most promising because it is specific for fluoride, has a relatively high fluoride exchange capacity, is not affected by chloride and sulphate concentrations normally found in water, and is easy to regenerate. In addition adsorption onto activated alumina is a proven, reliable, safe, simple process.

THE ACTIVATED ALUMINA PROCESS

Activated alumina (Al_2O_3) functions as an anion exchange material in the removal of fluoride. The process, which is carried out in a suitable column or vessel, may be represented as follows:

Loading (fluoride adsorption)

$$\text{Alumina.}H_2SO_4 + 2NaF \rightarrow \text{Alumina.}H_2F_2 + Na_2SO_4.$$

Loading is usually best performed under slightly acidic conditions (pH 5-6) to optimize fluoride adsorption. The product water is, therefore, slightly acidic but can be stabilized with either caustic soda, soda ash or lime.

Backwashing

This is carried out upwards to expand and redistribute the bed and prevent short-circuiting.

Regeneration (using a dilute caustic soda solution)*

$$\text{Alumina.}H_2F_2 + 3NaOH \rightarrow \text{Alumina.}NaOH + 2NaF + 2H_2O.$$

Neutralization

$$2\text{Alumina.}NaOH + 3H_2SO_4 \rightarrow 2\text{Alumina.}H_2SO_4 + Na_2SO_4 + 2H_2O.$$

The Alumina.H_2SO_4 is now ready for another adsorption cycle.

EVALUATION PROGRAMME

The activated alumina process was evaluated by the National Institute for Water Research using a pilot plant (32 m^3/d) on an underground water containing approximately 8 mg/ℓ of fluoride in order to -

- compare regeneration methods (caustic soda vs alum);
- determine the importance of feedwater pH adjustment before loading on process performance;
- establish design criteria for general use; and
- determine the economics of the process.

---

*Aluminium sulphate (alum) may also be used as a regenerant but, although this is a simpler process, it has been shown to result in a lower capacity for fluoride removal and is, therefore, not recommended[7].

CONCLUSIONS

- Fluoride can be reduced from approximately 8 to less than 1 mg/ℓ by the activated alumina process.
- Approximately twice as much product water of a better quality can be produced with soda than with alum as regenerant.
- The precipitation of a sparingly soluble aluminium-silica complex when using alum for regeneration appears to have an adverse influence on the adsorption capacity of the alumina.
- Silicate and hydroxyl ions compete with fluoride for exchange sites on the activated alumina when the pH value of the feed water is greater than 7. This effect is remedied by pH adjustment of the feed water to between 5 and 6.
- A water recovery of more than 90% is possible.
- Provision has to be made to dispose of the regenerant and rinse waters, which amount to about 10% of the water treated and contain high concentrations of fluoride, caustic soda and sodium sulphate.

DESIGN CRITERIA

The following design criteria are based on the use of ALCOA type F-1 activated alumina. They were derived from a pilot plant with a capacity of about 32 m^3/d of defluoridated water.

Activated alumina (ALCOA type F-1*)
Grading: 0,5 to 1,0 mm
Fluoride (F-) exchange capacity: 3,2 g/ℓ
Bed depth: 1,0 to 1,5 m

Feedwater retention (contact) time in column: 5 min minimum

Backwash (50% bed expansion desirable)
Flow rate (adjust as required): 980 $\ell.m^{-2}.min^{-1}$
Duration: 10 min (approx.)

Regenerant (aqueous caustic soda solution): 10 kg/m^3
Regenerant volume: 5 bed volumes**
Regenerant upflow rate: 100 $\ell.m^{-2}.min^{-1}$

Rinsing (after caustic soda regeneration)
Flow rate (downwards): 200 $\ell.m^{-2}.min^{-1}$
Period: 30 min (approx.)

Acid used for neutralization of alumina: 1,53 kg sulphuric acid (1,836 kg/ℓ) per m^3 feed water
Volume of dilute sulphuric acid required: approximately 15 BV (until pH is about 8)
Neutralizing acid flow rate (downward): 200 $\ell.m^{-2}.min^{-1}$

pH Adjustment of feed water to exchange column using dilute sulphuric acid
The amount of dilute (or concentrated) acid required must be determined by calculation or experimentally for each feed water. This may change from time to time and automatic pH control is therefore preferable

*The activated alumina used was obtained from ICI, 1 Leyds Street, Braamfontein, Johannesburg. (This firm is not necessarily the best supplier and any other firm may be approached.)
**1 bed volume = volume of alumina in column.

The output of defluoridated water per regeneration cycle depends on the fluoride concentration of the feed water. At a fluoride concentration of 8 mg/ℓ, approximately 400 bed volumes are produced.

The activated alumina deteriorates with time, due to abrasion and irreversible exchange reactions. A lifetime of about 4 years may be assumed, i.e. approximately 25% fresh alumina may have to be added annually.

COSTS

Total defluoridation costs for a 500 m^3/d (approx.) plant were determined at R0,33/m^3. These include amortization of R146 000 capital over 20 years at 10%/a interest. Also included are the costs of product water stabilization equipment, chlorination and labour, but excluded are those of product water storage and brine disposal. Costs are also affected by factors such as plant size, required regeneration frequency and safety factors. In the case quoted, regeneration was performed after 67 h loading (two regeneration cycles per week) and 25%/a alumina replacement was assumed. However, with more frequent regeneration, smaller equipment may be used for the same output, with a concomitant reduction in cost.

GAcsv 621/0868/8003

DEFLUORIDATION PLANT

In practice two columns were being installed so that one could be regenerated while the second was in the adsorption mode.

OPERATING PROCEDURE

1. Adsorption in fixed bed downflow mode with pH control by H_2SO_4 addition to maintain pH 5.5 at influent end. Adsorption capacity depleted when F^- at outlet is 1.5 mg/l of F^-.

2. Backwash to remove suspended solids accumulated in alumina bed.

3. Regenerate with 1% caustic solution.

4. Rinse, 30 minute upflow at 200 l/min/m².

5. Neutralize alumina with acid.

6. Back to Step 1.

SOURCE OF ALUMINA

Alcoa type F-1 supplied by ICI in South Africa. Alumina is also available from Alusuisse.

WASTE VOLUME

Waste volume is about 10% of the flow of feed. However, an opportunity to make recovery more efficient is the possible reduction of caustic regenerant solution from 5 bed volumes to 3 bed volumes which was shown in the pilot tests to be adequate. The effluent is used to transport tailings into the tailings dam.

PRODUCT QUALITY

Product with less than 1.5 ppm F^- is achieved consistently

OTHER FLUORIDE REMOVAL PLANTS

An alumina-based fluoride removal plant was designed and installed at the Leeupoort Recreation Farm near Rooiberg Mine at a cost of around R80,000. The owners of the farm needed a good water supply to be able to sell real estate.

The Leeupoort Recreation Farm installed the process without provision for acid dosing to adjust pH and CSIR staff predict that the system will fail.

Alumina-based fluoride removal plants are believed to be installed at Gila Bend, Arizona and at Bartlet, Texas. There is believed to be at least one other such plant in California.

PILOT PLANT PERFORMANCE

(Diagrams sketched and not to scale)

402 bv of product at less than 1.5 ppm F^- was recovered per cycle using NaOH regeneration compared with only 273 bv using alum to regenerate the alumina.

(Diagrams sketched and not to scale)

Silica adsorbs onto the alumina granules unless the pH is dropped to below 6. There is enough silica in the feedwater (12-14 ppm) to affect the F^- adsorption capacity of the alumina unless pH is dropped.

CHEMISTRY SENSITIVITY OF ALUMINA F^- REMOVAL

1. If NaOH is added to the raw water, magnesium hydroxide precipitates and flocculates out. The raw feed is scale forming.

2. Arsenic is adsorbed by the activated alumina and it adsorbs irreversibly so it is important that the feed should have no arsenic in it.

3. The activated alumina treated water at reduced pH 5-6 is very corrosive. NaOH is injected at the outlet of the process to maintain slightly scaling conditions.

Note on R. O. Pretreatment

The Leeupoort water is scale forming, and would foul an R. O. membrane. By using alum coagulant, diatomaceous earth and cartridge filters, plugging index can be reduced from 95% to 20%.

CONCLUSIONS

1. An effective and easy to operate activated alumina adsorption and regeneration pilot plant process has been developed and demonstrated for fluoride removal from water.

2. The performance of the actual commercial scale 500 m^3/d plant has not yet been fully evaluated. All indications are, however, that performance will meet the expectations in every single respect.

3. Interesting chemistry sensitivity and mechanisms are identified which must be taken into account in F^- removal by this process.

OPERATION SHULLSBURG MINE
SHULLSBURG, WISCONSIN
(CLOSED SINCE 1979)

COMPANY EAGLE PICHER INDUSTRIES, INC.

LOCATION Southwestern Wisconsin

INTRODUCTION

This minesite was not visited but is reported here based on a description by HOFFMAN (1984) because of the somewhat surprising water quality effects that closure of this mine seems to have had on the quality of the local aquifer.

Exploration and mining operations have been undertaken in this part of the Upper Mississippi Valley zinc-lead district since the 19th century. Extensive underground mining occurred for about 25 years south and west of Shullsburg until the closure of the Bearhole Mine in 1978 and the Shullsburg Mine in 1979. Groundwater quality deterioration was noted by nearby area residents about nine months after closure of the Shullsburg Mine.

Changes in groundwater chemistry believed to be the result of acid mine drainage mechanisms were construed to be responsible for altering associated private water supply quality.

NATURE OF GROUNDWATER CHANGES

Groundwater quality in the Galena-Platteville dolomite aquifer deteriorated due to significant increases in dissolved sulfate to 3500 mg/l. Other impacts were noted with an increase in iron to 65 ppm and lesser quantities of zinc, lead and arsenic.

IMPACT OF WATER QUALITY CHANGE

Water quality impact is primarily due to the high sulfate, some of which reached levels rendering the water impotable to humans and livestock. Dairy farms were especially susceptible.

GEOLOGY

The Shullsburg Mine complex is located in the Driftless area of Wisconsin. Glacial deposits are absent and the surface is characterized by rolling hills with local relief of 100-200 ft. Surface drainage patterns are controlled by geologic structure. Drainage divides are influenced by structural highs, minor folding and joint patterns.

Surface geology is characterized by Ordovician shale overlying the Galena dolomite. Subsurface geology includes the Galena, Decorah and Platteville dolomites overlying the St. Peter sandstone.

All the Ordovician units serve as aquifers, with the majority of wells finished in the Galena-Platteville dolomite or the St. Peter sandstone.

HYDROGEOLOGY

The hydrologic system is a combination of water table and artesian system. The water table system is present in all of the Shullsburg area, but local confinements may produce artesian conditions. Generally, groundwater divides follow surface divides; exceptions occur when pumping activities associated with mine dewatering alter the potentiometric surface. Groundwater flow in the shallow Galena-Platteville dolomite is fracture and joint controlled, typical of carbonate terrains. Groundwater which is recharged throughout the area discharges to streams and through springs.

Mine dewatering was necessary for operations in the Shullsburg region. The lead-zinc sulfide ores occur in the Galena-Platteville dolomite and thus are intimately associated with this upper bedrock aquifer. Large scale dewatering began in the 1950's and continued until closure in 1978-9. It is significant that the Shullsburg Mine was developed in close proximity to the groundwater divide that separated flows between the Galena River and Apple River basin. The development of a large cone of depression resulted in movement of the divide 2-3 miles northwest and southeast of the mining site.

Up to 20 million gpd were pumped during development phases of the 1950's. Flows of 8000 gpm were reported when mining proceded into new fracture systems. Pumping rates just prior to closure were 6.5 million gpd.

GROUNDWATER QUALITY

The groundwater was characterized in 1973 as a calcium-magnesium bicarbonate type, very hard, but suitable for most purposes. TDS were typically between 300-400 mg/l with total hardness accounting for about 90% of the dissolved load. Sulfate averaged 40 mg/l with a maximum reported value of 470 mg/l.

SHULLSBURG MINE

The Shullsburg Mine was the largest and most productive of the underground mines in the area. Sphalerite was the primary ore mineral with associated pyrite, marcasite, galena and calcite, typical of the fracture filling type of orebodies in the region.

Mineralization was not restricted to joints and fractures but also occurs as disseminated replacements up to 400 ft from the primary fracture filling. The mining excavations resulted in drifts following the productive veins. Access was by inclined shafts so ore was trucked from the working faces of the mine to the mill. Ore bodies were drilled, blasted and then worked with front end loaders. Many of the older mined out areas were reached with vertical shafts some of which are still open. Numerous springs and seeps have been noted in the fractured dolomite and it is likely that many or most fractures would yield water under recharge conditions.

Underground inspection in 1978 revealed that several fractures contained abundant sulfides, primarily pyrite and marcasite. A number of these were seen to be actively oxidizing with deposits of an orange gelatinous precipitate. Classic acid oxidation of FeS_2 as discussed in the chapter on Acid Mine Drainage, was occurring in the carbonate environment.

ACID MINE GEOCHEMISTRY

The chemistry of acid mine drainage is discussed in the chapter on the subject. BARNES & ROMBERGER (1968 reference uncertain) stressed the chemical aspects of acid mine drainage and suggest that special problems can occur if the acid product of the reactions are neutralized by dolomite.

Oxidation of sulfide minerals under conditions observed in the Shullsburg area can be described as follows:

Initial Reaction

$$FeS_2 + 2H_2O + 7O_2 = 2Fe^{2+} + 4H^+ + 4SO_4^{=}$$

This reaction is accompanied by minor amounts of metastable thiosulfate which also oxidizes to yield sulfuric acid. Under acid conditions iron sulfides are the most reactive followed by zinc and lead sulfides. The reaction for marcasite and pyrrhotite can be nine or ten times as fast as for pyrite.

In the presence of sulfuric acid and oxygen, ferrous sulfate oxidizes to form water soluble ferric sulfate.

$$4FeSO_4 + 2H_2SO_4 + O_2 = 2Fe(SO_4)_3 + H_2O$$

The kinetics of this reaction is greatly increased by the presence of T. ferroxidans bacteria.

The ferric ions react with water to form ferric hydroxide which yields additional sulfuric acid:

$$Fe^{3+} + 3(SO_4^{2-}) + 6H_2O = 2Fe(OH)_3 + 3H_2SO_4$$

The ferric ion can also oxidize additional iron sulfide to yield sulfuric acid and ferrous ions which energize the T. ferroxidans bacteria.

Ferrous sulfate can react with water to form melanterite $FeSO_4 \cdot 7H_2O$ and copiatite $Fe(OH)_2\ Fe_4\ (SO_4)_6 \cdot 20H_2O$.

The final major reaction involves neutralization of the sulfuric acid by the dolomitic host rock.

$$H_2SO_4 + CaMg(CO_3)_2 = MgSO_4 + Ca^{2+} + 2HCO_3^-$$
$$MgSO_4 = Mg^{++} + SO_4^=$$

The reaction is slowed by the coating effect of precipitated hydroxides and the slower reaction rates of dolomite with acid compared with calcite. This results in micro-environments within the dolomite fractures where acid mine drainage reactions could persist over extensive areas in the underground workings in the Shullsburg Mine.

An important consideration for water quality impacts is that $MgSO_4$ or epsom salts is almost 200 times as soluble as gypsum $CaSO_4$. Therefore, neutralization by dolomite can produce much greater levels of dissolved sulfate than might result from neutralization of calcite or limestone. Evidence of reaction between dolomite and acid mine drainage would be an increase in Mg^{2+} ions relative to calcium as well as elevated sulfate levels.

Water chemistry in the Galena-Platteville dolomite and in the underground workings as determined by C. L. R. HOLT of the U. S. Geological Survey are as follows.

	Fe (ppm)	Ca (ppm)	Mg (ppm)	HCO_3^- (ppm)	$SO_4^=$ (ppm)	Cl^- (ppm)
Galena-Platteville Aquifer	0.6	-	-	374	33	4.6
Galena-Platteville Mineworkings	0.14	113	61	395	203	4.4

SHULLSBURG

Within a year of closure of the mines some area residents noticed deteriorating water quality. Several dairy farms close to the Shullsburg Mine noted a significant drop in milk production. Water samples collected in response to complaints by the Wisconsin Dept. of Natural Resources confirmed elevated sulfate concentrations and associated magnesium, calcium, bicarbonate and iron. High levels of sulfate in the drinking water had both the human and dairy cow victims "on the trot."

Neither the mining company nor the Wisconsin Dept. of Natural Resources anticipated the possibility that cessation of pumping and reflooding the mine would adversely affect nearby private water supplies. Local residents claimed damages against the mining company for an amount in excess of $200,000 in the United States District Court.

Many of the sulfate values for samples of wells in the area exceed the 250 mg/l National Secondary Drinking Water Standard (Federal Registor 7-19-79) by an order of magnitude. Review of the data is believed to support the claim that the increased sulfate levels resulted from the flooding and solubilization of acid oxidation products precipitated in the dolomite fracture system.

Table 3 represents data from Evans, (1983), grouped according to location with respect to the recently active Shullsburg and Bearhole Mines, older mine areas, and the City of Shullsburg background area. This data was collected either in December of 1981 or March of 1982. It have been chosen because it represents the widest area distribtion of wells sampled in a reasonably close time frame. It is possible that the March data may be influenced by spring recharge conditions; however, given the magnitude of the differences between the control wells up gradient in the City of Shullsburg area, with the impacted wells in the mine area, the influence probably was significant.

1. The high sulfate concentrations in ground water associated with dolomitic aquifers in Southwestern Wisconsin appears to be the direct result of acid mine drainage associated with mines in the area.

2. Dewatering of the fractured rock exposed pyrite, marcasite and sphalerite to oxidation in non-saturated flow conditions.

3. Neutralization of sulfuric acid by dolomite produced highly soluble magnesium sulfate.

4. When mining stopped and pumping of water from the workings stopped, the workings were flooded and the exposed sulfates dissolved. Locally sulfate concentrations were increased to 100 times regional background levels rendering the affected groundwater non potable for human and livestock consumption.

5. Water quality data for the older mine area indicates a much lower level of sulfates and AMD products, probably due to the salts having been flushed out of the system which is now flooded.

6. The State of Wisconsin enacted a comprehensive ground water quality protection law in May 1984, and similar types of legislation have been enacted, proposed or planned for other states and the federal government. Ground water quality protection based on numerical standards such as the primary and secondary federal drinking water standards, or the suggested no-adverse response level of the federal EPA have been or are likely to become the basis for regulatory decision making.

   Formal programs of reference sample testing, quality control and chain of custody records will be subject to regulatory control.

   The Wisconsin approach has been to set two tier performance boundaries based on preventative action standards and enforcement standards. Implementation of these standards will require detailed water quality monitoring prior to the new activities in order to establish background conditions. Some fraction of Federal Drinking Water Standards are expected to become the litigation level. Water quality standards will have to be achieved within the property boundaries of new solid waste disposal facilities, and monitoring is likely to be required for all parameters which may be impacted.

The Shullsburg case of mineral rights and water rights raises an interesting situation. It would appear that in Wisconsin a mining company paying royalties to a landowner for mineral extraction will have to guarantee that associated groundwater will not be impacted or of supplying an alternative water supply. This burden will be carried by the company into post mining situations. The above is the opinion of Professor James I. Hoffman whose paper this description summarizes.

Important impact will be felt by long established mines when closure and reclamation applications are made. The Shullsburg litigation was settled out of court.

INTRODUCTION

Rehabilitation of the Wedge Mine is one of the pioneering cases where acid mine drainage damage has been prevented, and a sulfide ore minesite restored to an extent that it can be abandoned permanently. The need for perpetual operation of a treatment plant to treat acid mine drainage has been avoided.

Wedge Mine ore was treated at the nearby Heath Steele concentrator so there were no sulfide bearing mill tailings on the site. This simplified the task considerably. High pyrite wasterock on the site was disposed of however in the old mine excavation.

KUIT et al. (1977) described the challenge that presented itself at the Wedge and the measures that were taken to solve the problem. At the time the paper was written the rehabilitation project was not yet complete. The projected steps were in fact carried out in 1978/9 bringing total expenditures to $2 million.

KUIT (1984 personal communication) visited the site in 1984 and found that the natural revegetation over the clay cap and till cover has progressed beautifully.

This is one of the earliest first really successful mine, mill-waste restoration programs and it serves as a good example of what can be achieved. At a cost of $1 per ton ore removed, it indicates that today through proper planning the same results could be achieved at a much lower cost, if implemented as part of the operation. Finally, it does not provide much help in finding an answer to the bigger problem of permanently disposing of acid generating tailings from concentrates which is a subject deserving special attention in Canada today and in the future.

Abstract

Since closure in 1968, the Wedge Mine, situated adjacent to the Nepisiguit River in New Brunswick, has been flooding with acidic water containing toxic levels of heavy metals. Cominco Ltd. has undertaken a series of pollution control measures to mitigate the threat posed to the river quality. Included has been a successful treatment campaign in 1976 which discharged in excess of 30 million gallons of high-quality effluent from the accumulated volume of mine water.

The sources of contamination have been identified as actively leaching waste dumps. A comprehensive program of permanent corrective measures has been prepared which will culminate in mine backfilling. Once completed, the unacceptable burden of water treatment in perpetuity at a non-producing property will be removed.

Introduction

THE WEDGE PROPERTY, located about 30 miles inland from Bathurst, New Brunswick, was discovered in 1956 and mined by Cominco Ltd. from 1962 to 1968. Development and mining operations at the site and ore concentration in the Heath Steele mill 10 miles to the southwest have been described by Douglas.[1] Until exhaustion of ore reserves forced closure, total production amounted to 1.5 million tons at an average rate of 750 tons per day. The main production value was 3% Cu as chalcopyrite, but the total sulphide content was about 95%, with the bulk of the ore being fine-grained massive pyrite, a characteristic feature of much of New Brunswick's base metal mineralization.

During the operating life of the Wedge, environmental control requirements were relatively simple as compared with current standards, which are becoming more demanding. A relatively small flow of acidic mine drainage, averaging 50 gpm, was treated with lime from an underground station and pumped to the surface, where sludge composed principally of fine drill cuttings was settled in ponds. Decanted water then flowed into the Nepisiguit River, which is only about 1,000 feet down slope from the production shaft. The main purpose of this measure was to prevent river contamination by the drilling fines. The ponds containing this material were covered with lime, surface till and gravel when the mine ceased operations in 1968.

Subsequently, however, a mined-out stope began subsiding to the surface and a large open cave developed. This was accompanied by a sustained rise of water level within the underground workings and increasing soluble metal concentrations. In effect, closure was just the beginning of environmental problems originating with earlier mining activity, but the property was far from being left abandoned (as have many hundreds of similar short-lived operations across the country).

A critical element in the case of the Wedge has been the close proximity of the mine, its functional openings and the subsidence cave to the Nepisiguit River, as Figure 1 illustrates. The importance of defending this watercourse from contamination by uncontrolled, heavy-metal-containing acid mine drainage was recognized early by the New Brunswick and Federal authorities and Cominco Ltd. Prior to construction of a hydro-electric installation and other industrial development downstream from the mine, the river and its tributaries were a significant migratory spawning area for Atlantic salmon. The protection of the river is becoming a more acute requirement, as the Federal Department of Fisheries are planning to develop the

Walter J. Kuit was born and educated in British Columbia and since graduation in chemistry in 1966 has been employed by Cominco Ltd. He has conducted a range of chemical and metallurgical research assignments which, since 1972, have been mainly related to process development for effluent control from mining and metallurgical operations. He is currently a research chemist at Cominco's Technical Research Centre in Trail, B.C.

Harry E. Jackson graduated with an Honours degree in chemistry from London University, England, in 1939 and was with I.C.I. until he moved to Canada and joined Cominco Ltd. in 1952. In various assignments, he has had extensive experience in the research, development and application of various chemical and fertilizer products. He is currently senior research chemist at Cominco's Technical Research Centre in Trail, B.C., with main responsibility for effluent treatment and electrometallurgical research.

R. M. (Matt) Mattson was born in Greenwood, British Columbia and grew up in the mining camps of that area. Following graduation in mining engineering from the University of Idaho in 1942, he joined Cominco Ltd. and has held a number of positions in that company's mining operations in the Northern Territories and British Columbia, including that of senior mine engineer at the Sullivan Mine in Kimberley. He is currently senior mining project engineer in Cominco's Central Mines Group in Trail, B.C.

Nepisiguit's potential contribution to salmon resources provided that the interfering downstream factors can be overcome.

This paper provides a review of the various control measures that have been undertaken at the mine site to the end of 1976, an assessment of major factors contributing to post-production environmental problems and an outlook toward the implementation of a permanent corrective solution. The only alternative to this last item is the unacceptable situation of intermittent water treatment operating in perpetuity.

Ventilation Raise Sealing

Water infiltration to the mine and the leaching processes which solubilize toxic heavy metals continued since closure, but were without impact on the river until 1971, when site inspections revealed that seepage from the west ventilation raise (Fig. 1) was reaching the river. This increased during the spring runoff of 1972 to about 45 gpm and was at pH 2.9, containing 850 mgpl Zn and 7 mgpl Cu. It was at this time that New Brunswick and Federal authorities together with Cominco Ltd. agreed on the location of sampling stations above and below the mine on the Nepisiguit to monitor the impact of metals-containing drainage on river quality. Routine sampling commenced in May 1972 and data collected to the end of 1976 are discussed later in the paper.

An unsuccessful attempt was made to seal the raise in July 1972, but a second effort in December of that year resulted in the emplacement of a concrete plug with encased pipe and a valve that effectively prevented any drainage from the mine. This action only served to contain the problem, as the mine cavity was then a water-tight reservoir in which infiltrating volumes of contaminated drainage continued to accumulate. By the summer of 1973, the full magnitude of the problem became apparent and Cominco was requested to prepare contingency measures to deal with uncontrolled mine discharge that could possibly occur over the low point of the subsidence cave rim. Monitoring of the water accumulation indicated that level increases of more than 20 feet per year were experienced, with the bulk being in the spring months. Although the average annual precipitation in the area is less than 2.5 feet, the mine cavity must intercept surface and ground water originating some distance from the mine. The effective mine catchment area capacity is in the order of eight times (20 ft/2.5 ft) that provided by the underground workings.

In-Situ Liming Attempt

In the spring of 1974, the cave water level rose to 10 feet below the low point (total depth approximately 85 feet), and it was estimated that at least 60 million U.S. gallons had accumulated since closure in 1968. Following the consideration of various options, an operation (schematically illustrated in Fig. 2) was undertaken with the objective of neutralizing the contained mine water to about pH 8.5 by the addition of hydrated lime. This would effectively precipitate dissolved metals as a hydroxide sludge within the mine. To achieve efficient circulation, the water was pumped from the shaft, limed and returned to the mine via the subsidence cave. Based on the premise that leaching of heavy-metal sulphides would not occur at a significant rate in the flooded mine due to the slow availability of oxygen and high pH, it was expected that this program would:

— permit any immediate mine discharge to be of safe quality;

— afford a measure of sustained protection for several years.

The criterion for discharge related to the incipient lethal effects of Cu on salmonoid species,

was stipulated by the New Brunswick authorities as being that it should not cause a toxicity increase in the Nepisiguit River of more than 0.1 Toxic Unit of Cu. This system of definition arose from studies during the Northeastern New Brunswick Water Quality Program, which has been reviewed by Bell and Nancarrow.[3]

Although substantial metals reductions were achieved, the final project results, summarized in Table 1, demonstrate that the operation fell short of complete in-situ treatment. A total of 772 tons of hydrated lime were added, but it was subsequently estimated that to reach pH 8.5 and about the 1-mgpl level for all heavy metals, in the order of 1,800 tons would have been necessary. Various operating problems impeded the campaign, of which the most severe was corrosion by the cementation reaction of the soluble Cu in the raw water. A six-week shutdown was caused by the virtual destruction of mild steel lineshaft pump columns.

Following the operation's termination, it became apparent that reversion of the water quality was a confirmed trend. From depth sampling conducted by the Environmental Protection Service to April 1975, the average values for pH and Cu concentration given in Table 2 indicate that even complete treatment would have been only a temporary success. This phenomenon was believed to be caused by infiltration from sulphide-containing waste dumps above the mine and not by leaching from the flooded broken and in-place ore that remained underground, an interpretation indirectly supported by the following analysis of a surface dump puddle which collected after heavy rains.

pH	Cu	Zn	Fe
2.0	1,700 mgpl	2,000 mgpl	20,000 mgpl

Controlled Discharge and Treatment Progress in 1975

In order to avert a massive uncontrolled mine overflow during spring runoff, permission was obtained to conduct a limited discharge of accumulated water from the valve in the previously sealed west ventilation raise. The restriction on this emergency measure was that the combined impact of Cu and Zn was not to result in greater than 0.1 Toxic Unit in the Nepisiguit below the mine. This required that regulation of the rate of discharge be based on the metals concentration and the actual river flow. With daily discharge flow adjustments and increased river monitoring, the program was started on April 30 with the subsidence cave level at 7 feet to overflow and concluded June 7 after discharging 5.7 million U.S. gallons of mine water and lowering the water level to about 14 feet from overflow. Average heavy metals concentration of the discharge was:

Cu	Zn
60 mgpl	670 mgpl

Total river flow over the period was estimated at 13.8 $\times 10^{10}$ U.S. gallons, which yields a dilution factor of 24,000:1. Owing to channeling, average measured metals concentrations in the river, as shown in Table 3, indicated undesirable effects immediately below the mine, which caused fish kills in test cages, but the program had negligible over-all impact on downstream quality. In spite of this action having relieved the immediate pressures, it was evident that a further reduction of accumulated water was required in order to contain the mine infiltration anticipated in the spring of 1976. For this purpose, an operation (outlined in Fig. 3) was rapidly mobilized using essentially the same major facilities as in 1974, with the inclusion of a 200,000-gallon settling pond, 3,000 square feet in surface area, complete with a sludge pumping system. The plant was located on the waste dump near the mine shaft. By lime neutralization of raw water to pH 9.5, the objective of the campaign was to discharge 10 million gallons of treated pond overflow to the river, with metal hydroxide sludge return to the subsidence cave. Essentially, this plant was a rough field attempt at what is now considered conventional mechanized drainage treatment.

The main project parameters, given in Table 4, show that only 35% of the discharge objective was achieved over the 23-day operating period from September 5

to September 28, which [illegible]ered the subsidence cave water level to 20.5 feet from overflow. **Massive sludge volumes were a severe problem and this effect was reflected in plant efficiency, as only 24% of the water volume treated was actually discharged to the river.** Effluent quality was less than expected, but it was reported that a continuous bioassay by the placement of a fish cage directly in the discharge over the last 11 days showed 100% survival.

Hydrogeological and Waste-Dump Studies

Concern over continuing difficult treatment requirements at the Wedge property led Cominco Ltd. in early 1976 to retain Montreal Engineering Co. Ltd. for the purpose of conducting a hydrogeological assessment of the mine area and to recommend the most viable long-term solution to the problem. In their report to the company, this firm concurred with Cominco's conclusions that the major sources of the over-all hydraulic and leached metals accumulation, illustrated by Figure 4, were respectively:

— direct surface runoff and relatively shallow ground-water flow from a catchment area immediately up gradient from the mine;

— pyritic waste and development waste dumps immediately above the mine.

The recommendation submitted was that Cominco's program of mine backfill be undertaken, which, in summary, would include:

— submersion of chemically active surface dumps in the deepest accessible part of the mine;

— ground caving above the shallow stopes by drilling and blasting;

— substantial mine dewatering by treatment;

— backfilling with inert till and gravel;

— fill sealing with a compacted clay layer and placement of surface till.

From the standpoint of contaminant production, confidence was expressed that this course of action would recreate a hydrogeologic regime analagous, or even preferable, to the natural pre-mine situation. This would also satisfy concerns for public safety that had been expressed regarding the open subsidence cave.

The key element in the rationale on which the proposal was based was that the waste dumps were the source of water-soluble metals. Confirmatory leach studies were done in Cominco laboratories and these substantiated the contention. Both the estimated 18,000 tons of pyritic waste and the 65,000 tons of development waste in surface dumps were found to readily generate acidity and significant metals concentrations. Based on moisture content and contained soluble metals, Table 5 indicates the volume and quality of the water in the respective dumps at the time the samples were taken. The continuing impact of the dumps on the mine water quality would be controlled by the cyclic features of natural leaching. Alternating periods of precipitation or runoff and dry weather would be expected to flush and replenish the soluble metals. In an extensive study of abandoned New Brunswick tailings dumps, Boorman and Watson[9] concluded that seepage metals concentrations were largely controlled by availability of oxygen for sulphide oxidation. The exposure and permeability of the Wedge dumps

Fe	7,600 mgpl	760 mgpl

would provide adequate ventilation for the production of highly contaminated drainage.

1976 Dewatering and Treatment Program

Previous water treatment experience at the site demonstrated that a substantially improved plant was a prerequisite to meet the continuing threat of massive mine overflow and to support the several stages of complete rehabilitation that were being planned. Research and engineering studies were made of several alternatives which would overcome the most severe operating problems encountered in 1975 and permit a reasonably high rate of good-quality discharge from the mine.

A target objective for the 1976 campaign was set at 30 million U.S. gallons discharge, and a plant was designed and constructed to operate on the basis of the simplified flowsheet shown in Figure 5. In addition to diesel electric power generation and the lineshaft pump system (250-ft depth) in the mine shaft, major process components were:

— hydrated lime slurry preparation and storage incorporating a jet mixer, 10,000-gallon rail tank, air agitation and submersible pump for lime supply — no plant handling of dry lime;

— two 10,000-gallon reaction tanks in series (nominal retention time 20 minutes), equipped with aspirating pumps for mixing and partial oxidation of ferrous iron (Fe^{++});

— organic flocculant solution preparation followed by dilution prior to application in the reaction tank discharge launder;

— 200,00-gallon, 3,000-square-foot primary settling pond with an installed static underflow collection and pumping system with sludge return to the mine;

— a 30,000-gallon polishing pond before effluent overflow discharge to the river.

The total installed plant horsepower was 175 and primary settling pond effluent was used for all process water requirements.

Treatment commenced on July 12, 1976 and over the 78-day operating period achieved a total discharge volume of 30.6 million U.S. gallons, exceeding the objective. This lowered the mine water level by 46 feet, as illustrated in Figure 6. Based on the total volume treated of 64.6 million U.S. gallons, the average discharge efficiency during the campaign was only about 45%, but improved greatly from 30% at the start to about 80% at the end.

FIGURE 4 — Wedge Mine surface plan.

Although sludge flocculation was satisfactory, the high volumes collected in the primary settling pond (70% of total flow) during the early stages of operation were a severe problem and the original underflow pumping system had to be supplemented with a 4-in. diesel-driven unit. Treatment was intermittent, but sludge pumping was continuous to reduce pond accumulations. A second serious difficulty, common with most facilities treating water with high metals concentrations, was gypsum scaling throughout the plant following contact of lime with the raw water. This necessitated substantial maintenance downtime for manual descalling of equipment and piping. The system for supplying treated water to the plant was found to be particularly sensitive.

The quality of plant effluent discharged to the Nepisiguit River is shown by daily total metal concentrations of Cu, Zn and Fe over the 78-day operating period in Figure 7. Average pH was 9.8 and additional analyses showed Pb to be consistently less than 0.1 mgpl. Sampling by relatively untrained personnel under highly contaminated field conditions may have been a factor in the occasional high values, of which the most unfavourable were 1.5 mgpl Cu, 2.2 mgpl Zn and 14 mgpl Fe. Including these, however, the over-all treatment performance is regarded as being excellent, with the average effluent quality of:

Cu	Zn	Fe	Pb	pH
0.24 mgpl	0.58 mgpl	1.6 mgpl	<0.1 mgpl	9.8

These parameters compare well with the objectives set forth in the "National Guidelines/Regulations" for existing mining operations, which are (Fe not specified):

FIGURE 5 — 1976 Treatment Plant.

FIGURE 6 — 1976 operation — progress summary.

	Cu	Zn	Pb	pH
Daily Maximum	0.45 mgpl	0.75 mgpl	0.3 mgpl	minimum 5.5
Monthly Average	0.3 mgpl	0.5 mgpl	0.2 mgpl	minimum 6.0

In addition, the above requirements are accompanied by respective suspended solid standard levels of 37.5 and 25 mgpl, which in reality could not be tolerated if the metals parameters are to be satisfied in a treatment operation of this type. Soluble metals concentrations less than the objective levels can readily be attained by pH control at 9.5, but treatment sludge solids are metal hydroxides that will reflect in total metals analyses, usually proportionate to the corresponding raw water concentrations. Preparatory research studies indicated that the Wedge plant effluent had to contain consistently less than 5 mgpl suspended solids in order to satisfy the daily maximum metals parameters.

Total hydrated lime consumed over the 78-day operation was 940 tons, but actual process consump-

tion declined dramatically from 25 to 7 tons per million U.S. gallons of water treated, which corresponded to reduced metals concentrations in the mine water, as illustrated in Figure 8. This factor was of primary importance in greatly improved plant efficiency in the latter stages of the campaign, because sludge production, lime demand and metals concentrations are directly interrelated. Accompanied by increased pH from 3.5 to 7.5, the improved raw water quality was attributed to the dilution effects of the high volume of low-density sludge, which was about 95% treated water. Without being intended, the objective set for the previously discussed in-situ liming operation in 1974 came close to being attained.

Pyrite Waste Disposal and Future Rehabilitation

The substantial reduction of accumulated water volume achieved by the successful 1976 treatment campaign permitted Cominco Ltd. to start implementing corrective actions addressed to causes of the mine water problem. In October, a 90-foot-long drop raise of about 70-degrees inclination was driven from safe ground near the east ventilation raise (Fig. 1) to the deepest part of the stoped area. The 18,000 tons of pyritic waste were then placed under the surface of the remaining water using the drop raise as a chute. Submersion of the waste is expected to have a moderate impact on the metals content of the contained mine water, but fresh leaching will be prevented.

This action represents the start of the permanent rehabilitative measures to which Cominco Ltd. is committed. During this paper's preparation, planning of the subsequent stages was in progress and it was expected that a substantial portion of the project could be completed by the end of 1977. When concluded, this costly mine filling and surface restoration program will remove the potential threat to the Nepisiguit River and relieve the difficult burden of water treatment in perpetuity.

River Quality Monitoring

Since May 1972, Cominco Ltd. has conducted routine monitoring in the Wedge area, which has included the use of stations immediately above the mine and about ½ mile below on the Nepisiguit

above the confluence with Forty Mile Brook. Analytical data for Cu and Zn in the river water to the end of 1976 are presented in Table 6 as averages over six-month intervals, with anomalous values being rejected. The latter include samplings when significantly higher metals concentrations were apparent upstream and others where contamination caused obvious discrepancies.

With the exception of channeling problems in the 1975 controlled discharge program, which have been discussed, there has been no evidence since the sealing of the west ventilation raise that the mine has had significant downstream effects on water quality. Cu, the most toxic element, has been consistently low at both sampling stations. The averaged data shows Zn concentrations to be higher downstream, but most of the difference is due to the pre-raise sealing period. In any case, the over-all impact of the mine in this period is not believed to have been harmful to aquatic life in the Nepisiguit River.

Pollution Control Expenditures

Since closure of the mine in 1968, Cominco Ltd. has spent more than $700,000 on the various projects and support functions directed either to water treatment or to mitigating the pollution threat posed by the Wedge Mine. These are summarized in Table 7, and, including estimates for the remaining stages of mine rehabilitation, the total expenditure will amount to about $1,500,000, equivalent to $1.00 per ton of total production. It is noteworthy that these costs have come after the fact that production termination measures satisfied requirements existing at that time. If they could have been anticipated during the mine feasibility stage, the decision on property operation may well have been seriously affected.

FIGURE 8 — Mine water metals concentration — 1976 operation.

Summary

Since closure of the Wedge Mine in 1968, Cominco Ltd. has undertaken a series of pollution control measures at the site addressed to the problem of highly contaminated mine water. These have successfully protected the quality and aquatic life of the Nepisiguit River by either prevention of the uncontrolled discharge of highly toxic drainage or treatment to produce effluents of low metals content. The 1976 treatment campaign, in which 30.6 million gallons of accumulated water was discharged, is significant in that conventional liming treatment technology was viably adapted to a self-contained operation at a site without normal plant services. The high quality of effluent produced demonstrates that the objective levels of the National Guidelines/Regulations standards for existing mines can be satisfied at abandoned properties.

The source of the contaminated drainage problem has been identified as surface waste dumps that are actively leaching, and a plan for permanent mine rehabilitation is being implemented. This includes burial of the surface wastes in the mine and total backfilling of the accessible stopes. It is expected that once this course of action is completed the generation of contaminated drainage will be prevented and the burden of water treatment in perpetuity will be removed.

Acknowlegments

The authors gratefully extend appreciation to Cominco Ltd. for permission to submit this paper. Acknowledgment is also made to L. Tozer of Tozer Construction Ltd., Bathurst, New Brunswick, for his many contributions to the projects undertaken at the Wedge Mine.

INTRODUCTION

St. Joe Minerals operates a large electrothermic zinc refinery at Monaca , PA. This trip report describes a water treatment program brought into effect for this plant that achieved a 95% reduction in metals released to the environment in effluents from this plant.

A description by CULICK & BROCKMILLER (1980) outlines the program from 1970 to 1980. It is somewhat out of date because since it was written the Monaca operation has been trimmed considerably. Nonetheless, their paper is of importance because it shows what can be achieved using conventional lime precipitation and settling techniques. It also shows the importance of cutting back on water use and of segregating water flows to keep non-contact water separate from water that has been contaminated by metals.

In March-April 1984 a new regulation package governing non-ferrous metal smelters appeared in the Federal Register under the title: "Final Effluent Limitation Guideline, Non Ferrous Manufacturing - Non-Point Source Category." These Best Available Technology regulations under RCRA would require technology beyond lime-settle-filter. The new regulations placed restrictions on both the mass of metal that may be released in effluents and maximum allowable concentrations for these metals.

St. Joe Minerals Corporation together with other non ferrous metals producers filed a complaint and were in the process of supporting American Mining Congress litigation against the U.S. EPA.

Because of the sub-judice status of regulations governing non-ferrous smelters, the company was understandably not free at that time to discuss the subject in detail.

For non-ferrous metals refinery operations consisting of several consecutive processes, the total amount of metal contaminants that may be released in effluents is computed building-block fashion from a series of allowances for each part of the metal processing sequence. Since the regulations are interpreted to have been written for electrolytic plants, it was felt that several processing steps applicable to pyrometallurgical processing had been left out and that the net allowable levels of metals in effluents from plants such as at Monaca were impossibly low.

METALLURGICAL OPERATING UNITS : Roaster and Acid Plant
Sinter Plant
Electrothermic Zinc Plant
Chloride and Ammonia Removal Plant
Treating Sinter dusts

PROCESS WATER FLOWRATE : 1200 USgpm

FUTURE AIMS : St. Joe aims to be able to recycle more water within the plant, thereby reducing the amount of effluent requiring treatment.

WATER BALANCE

Water for use in the process is obtained from wells on the property which supply 1120 USgpm. About 80 gpm (average) stormwater is added to yield a total of 1200 USgpm to the settling lagoon and treatment plant.

Water is used in the metallurgical processes in two main places:

1) In the zinc vapor condensors where exit gases are scrubbed. Blue powder is formed and some chloride and zinc goes into solution.

2) In the sinter process bagfilter dust containing zinc and cadmium is treated at pH 10.5. About 50 gpm liquor is generated containing dissolved Zn, Cd, NH_4^+ and Cl^-.

TYPICAL EFFLUENT COMPOSITION (BEFORE & AFTER TREATMENT)

	Element	Mean	1 Day Max.	10 Day Max.	30 Day Max.
St. Joe - Influent	Zn	14.5	77.2	30.0	21.3
	Cd	2.4	16.7	6.2	3.9
	Pb	2.6	16.0	6.0	4.0
St. Joe - LS&F	Zn	0.55	3.34	1.24	0.75
	Cd	0.19	1.02	0.39	0.22
	Pb	0.07	0.45	0.17	0.12
	Flow	1200 gpm			

Note: All analyses expressed in ppm except as otherwise noted.

TREATMENT PROCESS

The water treatment process installed by St. Joe consists of the following steps:

1. Settling Lagoon with 2.5 million gallon surge capacity. Min 4' depth to 9.5' level.

2. Lime addition tank - Reactor 1

3. Lime addition tank - Reactor 2

4. CBI - Thickener - Clarifier

5. Overflow filtration units

6. Clarifier sludge recycle to the sinter plant

Settling Lagoon

The plastic lined settling lagoon is fitted with a center boom to provide a longer residence time for effluents. Three floating pumps are installed at the outlet end of the lagoon. At any one time two may be in use with one standby. Plant effluents as well as drainage and spills drain directly to the lagoon. Feedwater is usually at pH 7.5.

Chemical Contactor No. 1

Settled effluent water is pumped to mechanically agitated reactor No. 1 (12,000 gallon capacity) which is baffled. A magnetic flowmeter controls the flow to the reactor No. 1 and is regulated by the liquid level therein. A 5% lime slurry is added to maintain pH 8.8 in Reactor No. 1. Lime addition is controlled by a BIF Splitter made by BIF Division of General Signal Corporation, Warwick, R. I. which is pneumatically controlled.

Chemical Contactor No. 2

Overflow from Reactor No. 1 flows into Reactor No. 2 to which lime slurry is added via another BIF Splitter to bring the pH to 9. Sludge from the clarifier is returned to this tank. Overflow from Reactor No. 2 flows to the clarifier which is outdoors. Reactors 1 and 2 and reagent as well as flocculant makeup tanks are housed indoors.

Flocculant Addition

Calgon 3100 flocculant is added to the feed launder at 1 ppm dosage.

Clarification

The precipitated effluent is clarified in a 65' Ø 15' wall depth Walker Division of Chicago Bridge and Iron clarifier with radial launders. Sludge is either recycled to Reactor 2 or discharged to filters for further dewatering before being added to the sinter plant feed.

Initially the clarifier failed to achieve a clear overflow. Tests with bentonite addition to the lime to provide an aid in clarification were abandoned in favor of underflow sludge recycle as the overflow still contained too much suspended solids.

Initially underflow was recycled to increase sludge density but the sludge compacted to form a cake that could not be pumped.

The clarifier operation was modified to use a very shallow sludge blanket - just enough to feed the recycle pump. Thickener underflow recycle now achieves a very clear overflow effluent.

LIME SLURRY SYSTEM

Every day a new batch of flocculant is made up by dissolving 10-15 lbs of dry flocculant powder in stainless steel 400 gallon batch tanks. Two tanks are in use for this purpose. One tank is mixed and aged for 24 hours while the other tank is in use as a dispenser. Calgon 1P3100 flocculant costing $2.30/lb was being used in June 1984. The flocculant dosage is varied by changing the amount of dry polymer added to the 400 gallon mixing tank each day depending on the flow of effluent.

Milton Roy diaphram pumps are used for flocculant solution dosing and are found to be reliable.

It has been found that if the polymer addition system fails, a problem develops rapidly with the overflow clarity.

pH CONTROL

Lime addition is controlled by measuring the pH automatically. Solutions are usually saturated with carbonate and as the pH is increased $CaCO_3$ coats the electrodes. When this happens the slowdown in response can be observed in the pH chart recorders. Electrodes are then simply immersed in hydrochloric acid to clean them which immediately speeds up their response and brings the pH back under tight control.

UNILOC pH electrodes have been in use at the plant and have proven satisfactory.

FILTER PRESS

Six loads per week are typically dewatered in a Perrin filter press. Two loads on Mondays, Wednesdays and Fridays.

The dry cake contains about 50% moisture. On a dry basis the cake contains about 10% Zn and 1% Cd. The cake is returned to the roaster plant as secondary feed.

About 12 tons/week of wet sludge is generated.

MULTIMEDIA POLISHING FILTERS

Three Envirotech Multi-media 10' Ø filters using anthracite coal and sand media are employed in the plant. Two are in use and one on standby at any time. Each filter is backwashed every 8 hours. The biggest problem encountered is buildup of $CaCO_3$ on the media support grid, with the result that the filters have to be rebedded every 2-3 years. Possibly inhibited hydrochloric acid would make it possible to clear the calcite scale buildup more easily.

FLOW REGULATION

A Leeds and Northrup magnetic flowmeter is used to regulate the valve at the inflow to the system.

OPERATORS

The plant is unattended. A utility man from the acid plant passes through every 2 hours. Several alarms signal in the plant control room and also at the utility room to alert when the operation of the plant is out of balance.

The daylight shift utility man comes to operate and clean the filter press as needed to dewater the sludges.

SLUDGE PUMPS

Warren Rupp pumps are installed to pump the clarifier underflow to the filter presses. Two lines are installed. These require 90 psi compressed air.

DORRCO recessed impellor pumps are used to recirculate sludges to the #2 Reactor tank at about 50 gpm.

CONCLUSIONS

1. The Monaca plant of St. Joe Minerals is an excellent example of how metal contaminant levels in effluents can be reduced by careful housekeeping and segregation of flows. Water management must take into account both process water and runoff drainage as well as plant washdown all of which is likely to contain dissolved metals in the vicinity of an older pyrometallurgical plant.

2. The success achieved at Monaca is the result of adopting a systems approach to identify and analyze all streams of water that contribute metals to the effluent, and then rerouting them, reducing flows through controlling the use of water and segregating the flows as necessary. Ongoing efforts will result in further improvement.

3. St. Joe uses sludge recycle to achieve a clear overflow from the water treatment plant. Use of a deep sludge bed in the clarifier was found not to be possible due to compaction of the flocs into a cake that could not be pumped. For new installations RANDOL recommends that a high density sludge process be tested. The HDS process described elsewhere in this report requires recycled sludge to be mixed with lime ahead of lime addition to the feed water.

4. The proposed new BAT regulations for discharges from primary zinc under 40 CFR part 421 in the Federal Register March 8, 1984 were reviewed and main gist was grasped, the precise computation of allowed metals content from a typical plant was not clear. The main thrust is that sulfide precipitation and filtration would be required under BAT for primary zinc producers as well as further effluent volume reductions..

5. The proposed new regulations which would require, depending on how the building block formula is calculated, maximum daily discharges of 0.2-0.3 lb Zn/d and 0.1 lb Cd/d total in effluents appears to be extremely ambitious if not impossible for a plant of the size of St. Joe's Monaca facility. Even if more water is recycled and possibly more advanced precipitation methods applied e.g., HDS, coprecipitation and possibly polishing with sulfide precipitation or ion exchange it is questionable whether this target could be achieved. This would require new technologies and there are legitimate questions as to the cost/benefit to society as a whole of taking effluent limits quite so far especially as the new BAT regulations would also result in the generation of a hazardous waste sulfide precipitate which may or may not be recyclable in the process.

6. Reduction in cadmium levels to the very low sub ppm levels in the effluent is ascribed to carbonate precipitation rather than hydroxides. There is normally adequate carbonate in the water but after periods of heavy rain soda ash may be added to the effluent.

7. Industry representatives interested in reducing metal levels by water treatment are advised to contact St. Joe Minerals staff at Monaca, PA direct to discuss a variety of alternatives that have been considered and tested over the years.

8. Attention of designers of new effluent treatment plants is drawn to the NORANDA application of HDS; e.g., at Waite-Amulet described in this Appendix and also to the very much simplified flocculant makeup system employed by NORANDA acid mine drainage treatment plants.

LEAD-ZINC-TIN '80

MODERN WATER TREATMENT PRACTICE AT THE ZINC SMELTER OF THE ST. JOE ZINC COMPANY

Gary M. Gulick
Charles A. Brockmiller
St. Joe Zinc Company
Smelting Division
Monaca, Pennsylvania

The St. Joe Zinc Company completed in early 1979 a "lime and settle" water treatment plant for controlling zinc and cadmium metal discharges in the process water stream from the zinc smelting operation located near Pittsburgh, Pennsylvania. The successful start-up of the treatment facility was the last step in a complex 8-year program to bring zinc smelter discharges into compliance with EPA NPDES effluent limits. The compliance effort also required upgrading existing process equipment, installing settleable solids removal and spill control facilities, segregating "clean" water discharges from contaminated discharges, and closing the loop on an existing effluent quality control facility.

The problem of achieving compliance was approached in an orderly manner and solved in five phases by applying time-proven technology to specific aspects of a complex and challenging problem. The St. Joe effluent compliance effort demonstrates the significant environmental improvements which can be achieved by "older" metallurgical facilities when given challenging but achievable compliance schedules and when the governing regulatory agency has some flexibility in setting effluent limits so that the goals set can be attained. The overall zinc smelter compliance program resulted in a 30% reduction in the quantity of effluent discharged, a 90% reduction in the total suspended solids and cadmium discharged, and a 95% reduction in zinc discharged to the Ohio River.

Introduction

St. Joe Zinc Company operates a primary zinc smelter employing the electrothermic process to recover zinc from zinc sulfide ore concentrate (1). The smelter, located near Pittsburgh, Pennsylvania, has a rated capacity of 226,800 metric tons per year (MTPY) of zinc equivalent production. The primary products are zinc metal in various sizes of slabs, ingots and anodes, and multiple grades of zinc oxide produced by both the American and French processes. In 1978 a modestly sized zinc dust plant, employing the Imperial Smelting Corporation Ltd. electrothermal process, was started up at the zinc smelter to provide a domestic source for a zinc product with a rapidly expanding market (2). Major by-products include 317,500 MTPY of 66° Baumé sulfuric acid and about 450 MTPY of cadmium metal. The wide variety of pyro and hydrometallurgical and chemical processes employed in the zinc smelter provide many challenging environmental problems.

Recently the zinc smelter started up a "lime and settle" effluent treatment plant as a final step in bringing smelter effluent discharges into compliance with effluent limits set by the United States Environmental Protection Agency's (EPA) National Pollutant Discharge Elimination System (NPDES) program (3). The program to achieve compliance spanned about eight years and was carried out in five main phases. The basic steps in the phased compliance program were:

1. Installation of a facility to minimize total suspended solids discharge and to control spills which would adversely impact the quality of the effluent being discharged.

2. Segregation of the smelter sewer system so that slightly contaminated process water (noncontact cooling water) could be handled separately from severely contaminated process water.

3. Installation of new shell-and-tube heat exchangers in the acid plant scrubber liquor circuit to replace cascade type lead tube coolers thus decreasing the potential for noncontact cooling water contamination resulting from process liquor leakage from the old style coolers.

4. Minimization of process water discharges by installing an electrothermic furnace off-gas washer system recycle water facility.

5. Installation of a "lime and settle" facility to treat the process water effluent which could not be recycled or eliminated.

A detailed description of the design and operation of the "lime and settle" facility will be presented. However, since the compliance program evolved over a period of time, a review of the steps in the development of the compliance program will first be made to provide perspective for other industrial dischargers with similar problems.

Background

Under mandate from the Clean Water Act, the EPA was charged with developing a national program for control of effluents from municipal and industrial sources. Formulation of the program occurred in the early 1970's. To provide a clear reference point for evaluating the compliance program executed by the zinc smelter, 1970 will be used as a base year.

In 1970 the zinc smelter used a total of about 113.6 million liters per day (lpd) (30 MGD) of process water. Through the use of closed-loop recirculating systems and multiple uses of single pass water, the 1970 zinc smelter effluent discharge was limited to about 45.4 million lpd (12 MGD). All process water to be discharged flowed through a single sewer system which also collected and discharged storm water runoff. The typical quality of the zinc smelter effluent discharged in 1970 is summarized in Table I. While the 1970 zinc smelter effluent quality was far less than our present effluent limits, the 1970 effluent quality was substantially in compliance with ORSANCO* limits as administered by the Commonwealth of Pennsylvania Department of Environmental Resources (DER).

Table I. Typical Zinc Smelter Effluent Quality - 1970
Concentrations in mg/l

Parameter	Average	Range
Total Suspended Solids (TSS)	6.50	3.6 - 38.4
Zinc - Total	8.33	4.2 - 27.1
Zinc - Soluble	5.19	1.8 - 14.8
Cadmium - Total	0.32	0.17 - 0.75
Cadmium - Soluble	0.26	0.10 - 0.70
pH	7.2	3.0 - 8.1

In January 1971 the zinc smelter was informed of revisions in ORSANCO limits. Two of the revised limits significantly impacted zinc smelter effluents. The effluent limit for cadmium was decreased to $\leq$0.01 mg/l from a level of $\leq$0.50 mg/l. And all dischargers were to "substantially complete removal of settleable solids." This latter restriction was defined only as "removal to the lowest level attainable with current technology." Since cadmium discharges at the time averaged about 0.30 mg/l, the zinc smelter was presented with a formidable challenge in the area of effluent quality control.

To meet the challenge, St. Joe extensively reviewed zinc smelter water uses and discharges and studied effluent quality control alternatives available. The investigation of effluent quality control alternatives was focused in three areas:

1. Development of an end-of-line treatment process to control cadmium discharges and total suspended solids.

2. Development of design criteria for additional facilities to minimize total suspended solids discharges.

3. Assessment of the feasibility of converting the existing zinc smelter water supply- and-discharge system to a closed loop total recycle system.

---

*ORSANCO - Ohio River Valley Water Sanitation Commission - An organization whose members were states bordering the Ohio River and whose purpose was to develop uniform standards for sanitary and industrial discharges so that all users of the Ohio River would have equal opportunity for the use of good quality water and equal responsibility for the maintenance of that quality.

None of the effluent quality control investigations provided the zinc smelter with a clear path to compliance with the cadmium and total suspended solids limits imposed by ORSANCO.

Because of the large volume of effluent, end-of-line treatment focused on chemical addition systems. Laboratory treatability studies indicated that a form of the "lime and settle" process used for years in the mining industry was the most likely candidate for controlling cadmium discharges (4, 5). Operation of a 3.15 liter per second (lps) (50 GPM) pilot plant in 1971 to treat a slip-stream from the zinc smelter discharge resulted in significant decreases in both zinc and cadmium discharges. However, cadmium concentrations of $\leq$0.01 mg/l were not routinely achieved (see Table II) and the overall effluent quality varied greatly, most likely as a result of extreme variations in the quality of the zinc smelter effluent at the time. Two additional problems associated with the operation of a full-sized "lime and settle" treatment facility were foreseen. First, the high pH (>9.0) required for cadmium removal required neutralization with sulfuric acid prior to discharge--such sulfuric acid neutralization would increase the effluent sulfate content above specified limits. Second, if equalization facilities prior to the treatment plant were not installed, the plant would have to be able to respond instantly to a wide variation in flow since the process sewer system also served as the storm sewer system for the zinc smelter.

Table II. Typical "Lime and Settle" Pilot Plant Effluent
Quality Concentrations in mg/l

Parameter	Average	Range
Total Suspended Solids	No Data	
Zinc - Total	0.41	0.04 - 0.55
Zinc - Soluble	0.13	<0.01 - 0.44
Cadmium - Total	0.04	<0.01 - 0.28
Cadmium - Soluble	0.02	<0.01 - 0.08
pH	9.6	7.7 - 11.4

Development of design criteria for additional settleable solids control involved constructing a pilot settling pond with the same proportions as the anticipated full-sized facility and evaluating available filtration equipment. The results of tests conducted utilizing a slip-stream from the zinc smelter effluent discharge indicated that a pond with six hours' retention time provided optimum solids removal effecting about a 60% reduction in total suspended solids. Increasing the retention time or filtering the pond effluent did not measurably increase the removal of solids from the zinc smelter effluent.

Ideally the best form of effluent quality control is to eliminate the discharge. On this basis a detailed study of the zinc smelter water uses and effluent discharges was conducted to assess the feasibility of converting the existing distribution-discharge system to a total recycle system. The conclusion of this study was that the wide variety of metallurgical and chemical processes employed in the zinc smelter could not be accommodated in a closed loop system without significant revisions to many smelter processes. The concept, although perhaps technically possible, was not economically feasible. Data collected relative to the quantity and quality of discharges from various elements in the zinc smelter process, however, provided the key to achieving effluent discharge quality compliance.

Analysis of effluent discharges from various elements in the zinc smelter process (Table III) revealed that about 297 lps (4700 GPM) of the existing 536 lps (8500 GPM) smelter discharge was essentially noncontact cooling water and, thus, should require no treatment prior to discharge. Of the remaining 240 lps (3800 GPM), 202 lps (3200 GPM) was discharged from process gas washers used to scrub the last traces of zinc from electrothermic furnace off-gases. The washer stream already passed through a series of settling ponds for recovery of the metal values prior to discharge to the sewer system. The effluent from the furnace washer settling ponds accounted for about 57% of the total suspended solids, 90% of the zinc, and 47% of the cadmium discharges in the smelter effluent.

Table III. Typical Stream Analyses of 1970 Zinc Smelter Effluents

Parameter	Noncontact Cooling Water	Process Water: Furnace Washers	Process Water: All Others
Flow, lps	296.5	202	37.8
Zinc, mg/l	<0.5	20	10
Cadmium, mg/l	<0.05	0.40	2
Total Suspended Solids, mg/l	<1	10	31

Investigation revealed that with the installation of a clarifier ahead of the existing settling ponds--with polymer addition to accelerate settling--and then using the existing ponds to polish the clarifier effluent, the furnace washer system could be close looped with only about a 9.5 lps (150 GPM) blowdown stream to the existing sewer system. Therefore, if the furnace off-gas washer system was close looped and the 297 lps of clean water was discharged through a separate sewer system, a 47.3 lps (37.8 lps all other + 9.5 lps blowdown) stream of process water would remain which would require treatment prior to discharge.

Utilizing the information developed in the studies, St. Joe proposed a four-phase compliance plan to the DER as follows:

Phase 1

Immediately construct a settling pond to reduce the total suspended solids discharged from the smelter. The facility would consist of a 16 million liter (4,225,000 gallon) capacity primary pond to settle suspended solids and a 7.6 million liter (2,000,000 gallon) auxiliary pond into which the smelter discharge could be diverted in the event of a spill which would adversely affect effluent quality (9<pH<6).

Phase 2

Segregate the sewer system into noncontact cooling water discharges and process water discharges. The noncontact cooling water discharges would bypass the settling facility installation. (The Phase 1 and 2 proposals are shown schematically in Figure I.)

Phase 3

Install necessary clarification and pumping facilities to substantially remove the furnace off-gas washer system effluent from the zinc smelter effluent discharge.

FIGURE I. ZINC SMELTER EFFLUENT SOLIDS REMOVAL AND SPILL CONTROL FACILITIES

Phase 4

At the conclusion of Phases 1, 2, and 3, perform treatability studies on the process water discharge and install a treatment process using the best available technology to reduce cadmium levels to the lowest achievable concentration.

It was anticipated that the proposed program would take three to four years to complete. The DER accepted the compliance plan and St. Joe began construction. The impact of the completion of Phases 1, 2, and 3 on zinc smelter effluent quality is shown in Table IV. The actual facilities are shown in Figures II, III, and IV. The revised pond inlet and discharge pumping facilities to accommodate the "lime and settle" treatment plant are visible in Figure III.

Table IV. Improvement of Zinc Smelter Effluent Quality With Completion of Phased Compliance Program

	1970 Quality		At Completion of Phases 1 & 2			At Completion of Phase 3		
Parameter	mg/l	kg/d	mg/l	kg/d	% Red.	mg/l	kg/d	% Red.

Through this same period in time, the EPA under mandate from the Clean Water Act was formulating effluent limits and guidelines for various types of municipal and industrial dischargers. The zinc smelter participated in a number of surveys and studies relating to nonferrous smelter water usage and effluent quality. A lengthy period of negotiations followed during which NPDES effluent limits for the zinc smelter were evolved. The final form of the zinc smelter effluent limits with two stages of compliance is shown in Table V. During the negotiations with EPA, the zinc smelter continued with the compliance program developed for the DER. At the end of Phase 3, the anticipated reductions in contaminants had been achieved. One additional problem which became evident was inconsistent quality of non-contact cooling water. The cause of this was traced back to the periodic leaking of coolers in the acid plant operation. As a result of this discovery, the zinc smelter proceeded with a program to replace the old coolers with new shell-and-tube heat exchangers, which had a leak-free operating history, as part of the overall compliance effort. With Phases 1, 2, and 3 of the original compliance plan completed and an NPDES permit with fixed effluent limits and phased compliance dates in hand, the zinc smelter now began the Phase 4 program to determine the most effective treatment for the process water stream and bring the zinc smelter effluent quality into compliance with NPDES limits.

Table V. St. Joe Zinc Company Zinc Smelter NPDES Effluent Limits

	Time Interval			
	January 2, 1975-June 30, 1977		July 1, 1977-January 2, 1980	
Parameter	30-Day Average	Daily Max	30-Day Average	Daily Max
Cadmium, kg/d	5.73	13.1	3.25	6.50
Zinc, kg/d	219	874	28.4	85
Total Suspended Solids, kg/d	132	528	81*	161*
Arsenic, mg/l	-	0.05	-	0.05
Mercury, mg/l	-	0.005	-	0.005
pH	6-9	-	6-9	-
Temperature, °C	-	40.6	-	40.6

*Limits for total suspended solids only applies to process water discharge stream.

Process Water Treatment Plant Design

An intensive study was again conducted in 1976 to characterize zinc smelter effluents so that the best available technology could be defined for control of the process water stream. To complement the efforts of St. Joe personnel, an engineering consulting firm with a strong background in industrial effluent treatment was retained to conduct treatability studies; recommend a treatment process; and participate in the preparation of equipment specifications. After the treatability studies were completed, the consensus of those involved in the investigation was that a "lime and settle" process was the best available at the time. Cadmium removal was still proving to be a problem so cotreatment with sodium sulfide was recommended to improve cadmium removal.

Theory of "Lime and Settle" Process

Lime treatment has been the standard in the mining industry for many years and is, thus, extensively documented. In general lime is added to the effluent stream being treated until a pH of 9.0 or higher is achieved. At the elevated pH, the solubility of zinc and cadmium is reduced and metal hydroxides are formed. By the addition of flocculating agents to promote agglomeration, large particles can be formed which are amenable to settling.

In the case of cadmium, the solubility is not sufficiently reduced at a pH of 9.0 to achieve mandated effluent limits. The addition of sodium sulfide was recommended so that additional cadmium could be precipitated as a metal sulfide. Extensive literature exists indicating that, at or near neutral conditions, metal sulfides have much lower solubilities than the metal hydroxides (6, 7). Subsequent operating experience indicated that the precipitation of cadmium as cadmium sulfide was not effective in decreasing zinc smelter cadmium discharges.

External Factors Affecting Treatment Plant Design

Since the "lime and settle" process involved pH adjustment and clarifier operation, the need for relatively constant treatment plant flows to achieve consistent pH values and stable clarifier operation was recognized. At the time the zinc smelter process water discharge had increased to an average of 56.8 lps (900 GPM). Instantaneous flows throughout a day might vary from 25.2 lps (400 GPM) to 75.7 lps (1200 GPM), depending on the cycles of various operations within the smelter. Additionally, the zinc smelter process water sewer system also served as the storm sewer system. This necessitated the additional design criteria that the treatment plant be able to handle the rain water runoff from a 100-year storm.

To provide the constant flow necessary for good treatment plant operation, the primary settling pond, installed in Phase 1 of the compliance program, was to act as a surge facility between variations in the process/storm sewer water flow and the treatment plant. As originally designed, influent to the pond was distributed uniformly into one side of the pond, flowed around a dividing wall, and overflowed a 12.2 meter (40 ft) weir at the discharge of the pond (see Figure I). The head over the weir was about 1.5 centimeters. The nominal depth of the filled pond is 3.3 meters (10.75 ft). Therefore, at the start-up of the water treatment plant, flow to the plant would be at the maximum design rate until the pond level was lowered to a depth of 1.2 meters (4 ft). At that time the plant flow would be reduced to the average process water flow rate.

With the pond level at 1.2 meters of depth, approximately 10.7 million liters (2,830,000 gallons) of storage capacity is available. When heavy rains occur, the pond level will rise while the treatment plant flow is gradually increased in step-wise increments until the rain stops or the pond level starts to fall. As the pond level again approaches the 1.2 meter depth, treatment plant flow is decreased gradually to match process water flow. In the event of problems in the water treatment plant requiring a shutdown for maintenance, the pond storage capacity provides about two days of effluent retention at normal flows.

To protect the treatment plant from low pH excursions, the spill pond, also part of Phase 1 in the compliance schedule, was retained. If a pH of less than 6.0 is detected in the intercept sump, process water sewer flow is automatically diverted to the spill pond until the cause of the excursion is found and corrected. Caustic soda is then added to the spill pond until the pH rises to 7.0 or higher. The contents of the spill pond are then pumped back to the intercept sump for discharge into the primary pond.

Figure V shows the primary pond at the start-up of the water treatment plant. Note that the water level is already about 1.5 meters below the original discharge weir on the left so that all process water is passing through the treatment plant prior to discharge. Also note the floating inlet flume extending into the pond being used in place of the original inlet distribution weir. As the pond level is lowered, hypalon pond liner material cushioned by a sand bed is exposed. If the original inlet distribution weir were continued in service, the impingement of pond influent onto the exposed liner might result in displacement of the underlying sand bed which could lead to rips or tears in the liner material. The floating flume prevents direct impingement and thus protects the watertight integrity of the pond. The waste transfer pumps were also placed on a floating platform as a means of keeping the pond in operation during water treatment plant construction.

Figure V. Water Treatment Plant Waste Transfer Pumps

General Treatment Plant Operation

As shown in Figure VI, process water is pumped from the primary pond at a rate of 37.8-75.7 lps (600-1200 GPM), as conditions warrant, to the first of two 22,700 liter (6000 gallon) capacity continuously agitated neutralization tanks. The pH is raised to within about 0.2 pH units of the desired pH level by the addition of a 5% lime slurry. The first tank overflows by gravity to the second neutralization tank where a 5% lime slurry is added until the final pH level required is achieved. To provide nuclei for particle growth, a 1.6 lps (25 GPM) stream of underflow solids slurry is pumped from the clarifier to the second continuously agitated neutralization tank. The overflow of the second neutralization tank goes to the clarifier.

Prior to entering the clarifier, a polymer solution (coagulant aid) is injected into the process water stream to promote particle growth and settling. The clarifier is a solids contact design with a process stream retention time of 5 to 10 hours, depending on the treatment plant flow rate. The effluent from the clarifier flows by gravity into a 22,700 liter (6000 gallon) capacity filter feed tank ahead of the multimedia filters. The filter feed tank is used to smooth out variations in flow to the filters and also provides an overflow bypass in the event of a filter failure. From the filter feed tank, water is pumped through the multimedia filters into a 60,600 liter (16,000 gallon) capacity effluent storage tank. Two of the three multimedia filters are in use at the same time with the third on standby. Filter switching is done automatically on a timed cycle. The effluent storage tank provides a source of clean water for backwashing the multimedia filters, general treatment plant washing, lime slurrying, and polymer batching. Overflow from the effluent storage tank is discharged to the Ohio River. Filter backwash water as well as general wash-down water is discharged to the primary pond for retreatment prior to final discharge.

The plate and frame filter press is operated as necessary to maintain a uniform depth sludge bed in the clarifier. Current operation requires 3 to 4 filter press cycles per week. The filtrate is returned to the clarifier while the filter cake is discharged into a mobile container for disposal in a licensed industrial landfill. Figures VII, VIII, IX, and X show key pieces of water treatment plant operating equipment.

Unit Operation

Lime Storage System. Hydrated lime is delivered in 16-18 metric ton (18-20 short tons) loads by trucks with pneumatic unloading capability. Prior to initiating the truck unloading cycle, sufficient water is added to the lime storage tank (71,900 liter capacity) to result in a 40% lime slurry. During the unloading operation, water sprays are operated in the tank to prevent dusting. The lime storage tank (center foreground Figure VII) is continuously agitated. Care must be exercised in mixing the lime slurry since a slurry of >45% solids results in a paste which does not mix or flow predictably.

Lime Slurry System. For neutralizing the incoming process water stream, a 5% lime slurry is used. The lime slurry batches are made automatically in 1140 liter (300 gallon) units. A low level probe in the continuously agitated lime slurry dilution tank activates the cycle. A valve in the pipe from the lime storage tank opens and allows 40% lime slurry to enter the pump tank. When the equivalent of approximately 45 kilograms (100 pounds) of lime has been timed into the dilution tank, the valve is closed. Water is then added to the dilution tank until a high level probe is satisfied. Each time the batch cycle is activated, the event is recorded on a counter.

FIGURE VI. WATER TREATMENT PLANT PROCESS FLOW SCHEMATIC

Figure VII. Process Water Treatment Plant Facility

Figure VIII. Equipment Arrangement - Neutralization Tank in Upper Right - Control Room in Upper Left - Multimedia Filters in Lower Right

Figure IX. Multimedia Filters

Figure X. Plate and Frame Filter Press

By recording each lime slurry batch, a lime-use record is maintained. Current levels of operation require the use of about 320 kilograms (700 pounds) per day of lime.

Polymer Addition System. A batch of polymer solution (coagulant aid) is prepared daily by the treatment plant operator. The strength of the solution is determined by the water treatment plant flow rate. Extensive jar tests have indicated that Calgon WT-3100 polymer is the most effective coagulant aid for treating zinc smelter effluents. In preparing a polymer solution, no more than 9 kilograms (20 pounds) of polymer is diluted in 1520 liters (400 gallons) of water as a higher concentration of polymer results in a highly viscous solution which cannot readily be handled by the injection system. The polymer solution is injected into the neutralization tank effluent at a constant rate of one liter per minute. The desired dosage for optimum particle growth is in the range of 1.0-1.5 mg of polymer per liter of process water.

Clarifier Operation. Acceptable clarifier operation has been achieved by maintaining the sludge bed at the lowest practicable level. If an underflow sludge recycle stream were not required to provide nucleation material for the process water stream being treated, the clarifier could be operated with no sludge bed. The underflow sludge recycle system requires the clarifier to be operated with a sludge bed of sufficient depth to keep the clarifier underflow cone full of sludge.

Multimedia Filter Operation. Three multimedia filters, each about 3 meters (9 ft) in diameter, are utilized to polish the clarifier effluent. Two filters are on line at a time with the third being backwashed or on standby. Provision has been made in the existing multimedia pipe header system to accommodate additional filter equipment in the event additional process water treatment plant capacity should be required. The filter media consists of a 30.5 centimeter (12 inches) deep bed of sand covered by a 45.7 centimeter (18 inches) deep bed of 24 mesh anthracite coal. The filters may be backwashed on a regular cycle or whenever a specified filter pressure drop is reached. The filters are currently being operated on a 16-hour time cycle with a pressure drop override in the event a clarifier upset causes solids carryover to prematurely plug the filters.

Clarifier Sludge Filter Press Operation. The operating cycle of the filter press is determined by sludge accumulation in the clarifier, which can be correlated with lime usage. Presently one filter press cycle is required for every 11 lime slurry batches prepared. The filtrate is returned to the clarifier. The filter cake, about 0.85-1.0 cubic meters weighing 1590 kilograms (30-35 cubic feet - 3500 pounds) of 50% by weight solids material, is dropped into a mobile container for disposal in a local licensed industrial landfill. The filter cake, which contains about 35% zinc on a dry basis, is not recycled to the zinc smelter because the water treatment chemicals used are not compatible with the electrothermic process.

Staffing. The operation of the process water treatment plant is the responsibility of the zinc smelter acid plant personnel. No additional personnel have been required to support the operation of the water treatment plant. The acid plant operator makes a regular walk-through inspection of the water treatment plant about four times per shift as part of his normal routine. The acid plant control room has a remote annunciator panel to alert the operator to any abnormal conditions. Since stable operation has been achieved, the process water treatment plant has required only minimal attention.

Water Treatment Facility Start-up Problems

When the process water treatment plant was started up at the beginning of 1979, effluent quality was not good enough to comply with NPDES limits. The problem seemed to be the result of solids carryover from the clarifier since the floc did not attain sufficient size for settling. This was related to insufficient particulate matter in the influent stream for proper nucleation. Initially there was no underflow sludge pumping back to the clarifier influent stream since no provision had been made for sludge recycling in the original treatment facility design. The carryover from the clarifier resulted in short multimedia filter cycles due to filter bed plugging.

In an attempt to provide material for nucleation, a bentonite slurry was made using the lime slurry solution as a carrier. The addition of the bentonite material resulted in an incremental improvement in effluent quality, but the improvement was not sufficient to achieve NPDES compliance. Finally by using a spare clarifier sludge filter press feed pump, clarifier underflow sludge recycle was initiated and the improvement in water treatment plant effluent quality was immediate and dramatic.

After initiating clarifier underflow sludge recycle, cadmium control remained a modest problem. Increasing the sodium sulfide dosage did not achieve any recognizable incremental reduction in effluent cadmium concentrations over lower dosages. Finally acting on speculative comments in the report summarizing the operation of the pilot "lime and settle" treatment plant many years before, the addition of sodium sulfide was terminated. Although cadmium in the water treatment plant effluent was then reduced, several other changes were made at the same time, so it is difficult to assess how much impact terminating the sodium sulfide had on reducing cadmium levels. Even if the sodium sulfide was not interferring with the reaction taking place, it offered no benefit in achieving additional reduction in cadmium levels in the zinc smelter effluent and, therefore, was not required. The precipitation of cadmium carbonate appears to be the primary reaction for the removal of cadmium from zinc smelter process water discharges. The carbonate ion is available for reaction since the zinc smelter water supply is relatively hard. In periods of heavy rain, the addition of a soda ash to the incoming process water may prove necessary to maintain the concentration of carbonate ions at a level sufficient to control cadmium discharges.

During the first few months of process water treatment plant operation, problems also occurred in determining the proper sludge depth to be maintained in the clarifier to achieve optimum unit operation. On the basis of jar tests and experience with similar installations, the consultant had recommended a 2.1 meter (relative to the clarifier side wall) bed depth. The purpose of this was to provide solids contact with the incoming effluent to promote particle growth and eliminate the need for underflow recycle. The 2.1 meter sludge bed depth was thought possible because the treatability studies found that the resulting settled material remained light and fluffy with minimal bed compression. In actual operation, however, the bed not only compressed, but formed a cake which the clarifier rake could not break. After the first four months of operation, it was necessary to drain the clarifier and manually remove the cake. Since then the clarifier has been operated maintaining only a bed of sufficient depth to provide material for underflow recycle. The differences in the predicted sludge characteristics and the actual sludge are most likely the result of the actual influent containing lower concentrations of contaminants than the water used in the treatability studies. The inference is that the clarifier is conservatively sized and is probably capable of handling an equal volume process stream with substantially higher concentrations of contaminants.

Treatment Plant Performance

Since stable operation has been achieved, the process water treatment plant has proved very effective in reducing zinc and cadmium levels as indicated by typical analyses shown in Table VI.

Table VI. Typical Process Water Treatment Plant Performance Concentrations in mg/l

Parameter	Influent	Effluent
Zinc - Total	22.3	<0.66
Cadmium - Total	0.61	<0.06

The treatment plant effectively removes >97% of the incoming zinc and >90% of the cadmium. The "lime and settle" process is capable of achieving consistent zinc concentrations in the treatment plant effluent regardless of zinc loading in the influent stream. Extremely high levels of zinc, however, tax the capacity of the neutralization equipment and require excessive sludge filter press operation. Control of cadmium has been sufficient to consistently meet NPDES permit requirements, but the quality of the effluent relative to cadmium has been more variable than that of zinc. This is because cadmium solubility is more sensitive to variations in pH than zinc in the pH range in which the water treatment plant operates. The "lime and settle" process has proven to be an extremely versatile operation for controlling zinc smelter process effluent quality. With a properly controlled feed stream, the "lime and settle" process appears capable of consistently meeting current zinc smelter effluent limit requirements.

Smelter Compliance

With the changes in cooling equipment in the acid plant operation and the completion of the water treatment plant, the smelter effluent discharge was brought into compliance with current EPA NPDES effluent limits as shown in Table VII. Total suspended solids discharges have been reduced by nearly 90% from 1970 levels while zinc and cadmium have both been reduced by greater than 90%. As a result the smelter effluent discharges are well within current NPDES limits. To effect these reductions, considerable effort was necessary requiring a complex five-phase program to achieve compliance:

1. Installation of a facility to minimize total suspended solids discharges and control spills (Figure 1).
2. Segregation of the zinc smelter effluents into noncontact cooling water and process/storm water sewer systems.
3. Installation of new heat exchangers in the acid plant operation to minimize the potential for noncontact cooling water contamination.
4. Minimization of process water discharges by installing a furnace off-gas washer recycle water facility.
5. Installation of a "lime and settle" process to treat remaining process water.

Table VII. Typical Zinc Smelter Effluent Quality

	1970 Smelter Effluent		1979 Smelter Effluent			Current NPDES Limits
	mg/l	kg/d	mg/l	kg/d	% Red.	Avg
Cadmium	0.32	15.0	0.04	1.31	91	3.25 kg/d
Zinc	8.33	385.6	0.48	15.70	96	28.40 kg/d
TSS	6.50	301.2	1.12	36.63*	88	81.0 kg/d*
Arsenic	<0.05	-	<0.005	-	-	0.05 mg/l Max
Mercury	<0.005	-	<0.0002	-	-	0.005 mg/l Max
pH	7.2	-	7.8	-	-	6-9
Temp, °C	<40.6	-	<40.6	-	-	40.6 Max
Smelter Discharge, lps	536		378		29	

*Current NPDES limit applies only to process water discharge; smelter effluent value reflects combined zinc smelter discharge.

The zinc smelter NPDES compliance effort required a capital expenditure of about $4,780,000 with the "lime and settle" process/storm water treatment facility accounting for $2,160,000 of the total. The estimated annual operating and maintenance cost for the "lime and settle" facility is $150,000. The total zinc smelter annual direct operating and maintenance costs for all the facilities installed as part of the NPDES compliance program are about $450,000. To insure continuous compliance with NPDES limits, an extensive effluent discharge monitoring system is operated which adds an additional indirect cost of $150,000 per year to the cost of compliance.

The installation of facilities to control zinc smelter effluent discharge quality may be complete, but the maintenance of compliance requires a continuing effort on the part of many groups. Operating departments within the smelter must wisely use water and insure discharges go into the proper sewer system. Engineering personnel must carefully review water uses in new projects and incorporate water use conservation measures into new facilities and minimize discharges through reuse of process water. Water treatment plant operating personnel must maintain the physical plant in good operating condition; optimize the process to achieve maximum contaminant reduction; and, along with environment control personnel, continuously monitor the actual performance of the treatment facility.

INTRODUCTION

Zincor treats a zinc concentrate from Black Mountain, Prieska and Rosh Pinah located in the northern Cape Province and Namibia/South West Africa. Concentrates are roasted and then leached in sulfuric acid followed by electrowinning after electrolyte purification.

Although acid is recycled, there are residues which must be disposed of or stockpiled and liquid effluents to be disposed of, as any runoff or spillage is pumped to an effluent treatment plant.

Of interest in this investigation is the Zincor experience with gypsum scaling and how to live with it.

PRODUCTION RATE

Zincor is a small electrolytic zinc refinery by world standards. Capacity is 8,000t Zn slab per month.

WATER CONSUMPTION

Current water consumption is 15 m^3 water per ton of zinc slab produced. Formerly the water needs were 22 m^3/t Zn but these were reduced through recyling of water. A water consumption as low as 13 m^3/t Zn has been achieved at times but operating staff find 15 m^3/t Zn to be more comfortable.

WATER UTILIZATION

Much of the water consumed is used for evaporative cooling in the plant both in the acid plants and the cell house. Solution is bled also to reduce the gypsum loading.

WATER COST R0.23/m^3 R29,200/mo R350,000/year

METALLURGICAL PROCESS

Zinc sulfide concentrate is roasted in a series of Lurgi fluid bed roasters. Two older units at 117 tpd each and two newer units at 200 tpd each make sulfuric acid in two Monsanto acid plants.

The calcine is leached in recycled H_2SO_4 spent electrolyte with added H_2SO_4. The acid strength is maintained at 1.5 gpl in the first leach tank. Above that concentration excess iron leaches. The acid rides out to a basicity of 0.5 in the last leach tank. The leached slurry is thickened to yield a zinc solution which is filtered and then purified to remove copper, cobalt and cadmium in successive steps prior to electrowinning.

The primary thickener underflow is leached in hot sulfuric acid at 80°C and 20-40 g H_2SO_4/l to dissolve residual zinc and iron from the zinc ferrites that did not dissolve in the primary leach. The hot acid leach pulp is filtered and by adding calcine to the filtrate, iron is precipitated at pH 2.35 which requires close control. This is a Zincor patent. The precipitated iron oxide residue is stockpiled - it is potentially suitable as a catalyst for SASOL. The solution filtered from the iron oxide is recycled to the first stage neutral each tank.

The remaining leach residue is next treated by a super hot leach at 90-95°C and 120-140 g/l H_2SO_4 to recover some additional zinc values which are filtered and recycled to the hot leach step. The residue containing 0.07% (21 oz) Ag/t and lead is stockpiled.

The zinc solutions after iron oxide removal is treated in three purification stages. Firstly copper and cadmium is precipitated with zinc dust. pH is controlled at 4.5.

Next cobalt is precipitated by adding zinc dust, arsenic oxide and spent electrolyte to maintain pH at 4.5. Finally cadmium is precipitated by zinc dust and $CuSO_4$ addition. pH is maintained at 4.5 by spent electrolyte addition.

ZINCOR ELECTROLYTIC ZINC PROCESS
BASIC PROCESS

The stage II cobalt-arsenic sludge is stockpiled. The Stage III cadmium is mixed with the Stage I Cu-Cd residue to obtain a 50-60% Cu-Cd cake which will be used to make a $CuSO_4$ product and cadmium metal sponge which is compacted and melted.

PLANTSITE

The Zincor electrolytic zinc plant is located at the old Vogelstriusbult gold-uranium plantsite. Effluents and tailings are discharged to an effluent site located within the old gold mine tailings dump. The Pb-Ag decant dams are located on top of the old gold plant slimes dam.

ROASTERS

There are four Lurgi fluid bed roasters. Two older 117 tpd units and new 200 tpd units.

WASTE HEAT RECOUPERATION

Waste heat recouperation boilers are installed. Two were installed by Deutsche Babock which use gradual cooling in series and experience less SO_4 formation. These have a rapping mechanism and Air Lance.

These are Oschatz units in parallel. These are scale free with low solids buildup.

SO_2 SCRUBBER

A normal open tower humidifier followed by a plastic packed gas cooling tower is used. In this weak concentration of H_2SO_4, zinc, fluorides and total dissolved solids are controlled by a continuous bleedoff that is pumped to the effluent plant.

GYPSUM CONTROL

The whole circuit is saturated with gypsum. Once a month the tank house circuit is shut down to remove gypsum accumulations from launders, pipes, etc. Typical solutions run 2500 mg $CaSO_4$/l. Cooling towers are de-scaled on a scheduled program.

Zincor was investigating the use of polyurethane pigs and sequestering agents for gypsum control in the pipes. "Pigs" are offered by:

1) Amforce Pty Ltd. offered through R. J. Spargo (Pty) Ltd.
2) RSA Pipe Cleaning (Pty) Ltd., Potchefstroom

In acid circuits the gypsum is soft as opposed to gypsum scale in alkaline circuits.

Formerly more water was jetisoned from the circuit to control scaling but subsequently water has had to be conserved because of the drought and a reduction from 22 m^3/t Zn to 15 m^3/t zinc production has been achieved.

One way to remove gypsum scale has been to burn scrap rubber in the steel pipes but this is "labor intensive." This is no longer done at Zincor due to air pollution considerations.

ANIKEM 4370 sequestering agents as used at East Driefontein Gold Mining Company was under consideration to help control gypsum. This reagent has a crysilic acid base. Another gypsum scale reducing reagent has been offered by:

Watercare Technical Services
P. O. Box 312
Gallo Manor 2052

Telephone: (011) 802-2320
Contact: Brian Bignam

Zincor metallurgical staff described previous experience at West Driefontein in raffinate pumping after neutralization which had a bad scale problem until the steel pipe was replaced by HDPE. The plastic pipe was supported at intervals and due to expansion/contraction the pipe would flex and become self-cleaning.

Soft rubber pipes are used from the V-M header tanks. When these scale up, the problem is solved by turning the flow off and collapsing the pipe to break the scale.

In West Germany, Ruhrzink uses pinchvalves on the cooling towers which are self cleaning. The cooling towers are used to cool down the electrolyte during electrowinning.

At Zincor forced updraft cooling towers are used. Heavy gauge PVC flaps are suspended on the sides. Gypsum forms in sheets on the plastic and slides off the slippery plastic surface. Prior to using plastic flaps there used to be a heavy gypsum buildup requiring a heavy support structure. About 14% of the water in the electrolyte solutions is lost to evaporation.

EFFLUENT DISCHARGE

After lime treatment to recover $Zn(OH)_2$ from the magnesium bleed spent electrolyte, the solution is pumped to the effluent treatment plant and together with other effluent solutions, it is treated to precipitate metals. A portion of the treated effluent is reused in the plant and the rest irrigated to the surface of the old gold tailings to dispose of it.

Stormwater goes to a stormwater drain fitted with a pH probe and automated gates. If the pH is within a dischargeable range the stormwater is discharged to Blesbokspruit which ultimately flows into the Vaaldam. If the pH is low, the flow is directed automatically to the emergency dam from which it is returned to the effluent treatment plant.

WATER BALANCE

Attempts to develop an accurate water balance have not been successful. A considerable quantity of water could not be accounted for. Accurate measurement is virtually impossible because of the lack of suitable instrumentation.

NUMBER OF WORKERS

The semiskilled worker compound houses 630. This is hooked up to the municipal sewage treatment works at Springs.

WATER SOURCE

In early 1984 Rand Water Board was supplying Zincor. A promising effort was being made to replace RWB water with Springwater from their own property. Two wells have been sunk which yielded reasonable quality water.

Note: Considering high TDS seepage in the effluent disposal area it would be interesting to see whether the water quality remains good from these wells.

RECYCLE

The iron residue filtrate is repulped using effluent water. Reclaimed effluent water is also used for cooling the roaster bed and for road dust control. Calcium and magnesium may be added to the calciner and it ends up in the magnesium precipitation plant.

Several cooling systems have been installed on the plant to cool and recycle water locally. Steam condensate is now returned to the acid plant where it is used to heat up zinc solutions. There is some concern about copper contamination. Pb-Ag residues from final stage leaching are repulped with reclaimed effluent water.

WATER TREATMENT

Zincor employs two water demineralizers using ion exchange following lime-soda softening to produce water for special applications.

Filtomat units were installed to clean cooling water in the acid plant to remove suspended solids (mainly unreacted ZnS, calcine, etc.). The filtomats gave lots of trouble and wasted "too much" water with the discharge of solids.

Excess water from the lined emergency water dam is treated in the effluent treatment plant with lime to pH 10.5 which precipitates Mg, Fe and everything else except $CaSO_4$.

ENVIRONMENTAL

Monitor wells are installed around the effluent and tailings area over which effluents are spray irrigated. Monitor well samples are regularly sent to the Department of Environment's slimes dam inspector so far with always low metal values.

There has been some request for a seepage collection drain to collect runoff and seepage before it can reach an adjacent bird sanctuary.

Effluent water after lime treatment to pH 10.5, thickening is sprayed onto the East Daggafontein slimes dam which practice has been approved by the Dept. of the Environment. Galvanized irrigation pipes and rainbird sprinklers are used. These pipes tend to corrode rather than clog up due to the pumping of this solution.

The slimes dam inspector with jurisdiction over the Zincor operation is Mr. Greenblatt from the Government Mining Engineer's office in Heidelberg.

Monitor well samples are taken by Zincor and analyzed in-house before being reported. Half the monitor wells are dry so no samples are collected.

CONCLUSIONS

Due to the recent concern in South Africa about the effects of high TDS effluents contaminating groundwater, it remains to be seen what effects disposal of tailings and high TDS effluents - (albeit low in metal values) have on groundwater in the local aquifers below the tailings piles. The missing water in the water balance attempts may be searched for in seepage.

Gypsum problems may be resolvable together with a much enhanced water recycling program by using seeded slurry R. O. desalination, but this is unlikely to be competitive with adding fresh water as long as it is available at R0.23/m^3 and as long as excess water can be bled with high TDS.

Stormwater drainage release to the spruit and the Vaaldam deserves careful in-house scrutiny from the point of view of pointsource contribution of dissolved solids and metals. Details of effluent discharge regulations were not scrutinized.

It is remarkable that such a large hydrometallurgical base metal plant can operate with such minimal environmental problems as indicated by Zincor. Generally jarosite residues are known to be difficult to contain without experiencing metal contamination. Zincor's water conservation program has made big improvements but it is believed that they will ultimately develop a water management plan that consumes less than the current 15 m^3 H_2O per ton zinc produced, but a careful water balance model is needed to devise such a plan.

Sulfates in the presence of magnesium can get to very high levels in water without precipitating $MgSO_4$. Water is generally unusable for agriculture or human consumption when the $SO_4^{=}$ levels get high enough . Treatment of excess water that accumulates in the lined "emergency" dam with lime to pH 10.5 is one way to remove all TDS except $CaSO_4$ and alkali metals.

In general, considering the large flows of high TDS solutions and disposal of precipitates and residues in the tailings area divided into "acid valley" for iron residues, "lead valley" for Pb-Ag residues and the evaporation area, it would be surprising if there were not serious groundwater contamination potentials - These may not be regulated for the time being, but judging by US trends the time is likely not too far off when groundwater protection becomes an important issue in South Africa as well.

INTRODUCTION

The Old Coronation Coal Mine at Kromdraai, Transvaal ceased production around 1970. The minesite was restored but significant volumes of acid mine drainage (AMD) water flowed to the surface at pH 2.2-2.4. In 1974 the flow of AMD was 3.0 mm Igpd (14,000 m^3/d) with a total dissolved solids level of 1750 ppm and conductivity of 180 mS/m.

HDS PLANT
OLD CORONATION MINE, KROMDRAAI

Numerous methods were evaluated for the disposal of this water as described by BOSMAN (1974). Initial attempts at lime neutralization and settling yielded a precipitate with a volume equal to 10% of the feedwater with further densification possible to 4% of the original volume of water treated. Since the mine was estimated to contain 10,000 tons of precipitable solids the volume of the sludge at 2.5% solids would be 400,000 m^3 requiring a costly surface dam. Disposal of the sludge underground was also unwise as it was not known how much of the sludge would redissolve and because this practice would interfere with possible future open cast mining of the pillars.

After pilot tests described by BOSMAN (1974) to test the high density sludge process (HDS) originally developed by Bethlehem Steel Corp. as described by KOSTENBAEDER & HAINES (1970) and the NALCO Water Treatment Handbook, a plant was installed at the Kromdraai site to treat 14,000m^3/d of acid mine drainage. This plant is described by BOSMAN (1983).

The HDS plant at Kromdraai was visited on 20 December, 1983 with a view to learning more about the performance, design and operation in practice of such a plant. A flow sheet showing pumps, meters and valves is provided. Detailed accounts of the pilot testwork and performance of the plant are provided in the Chapter on Acid Mine Drainage Treatment.

OBSERVATIONS

1. The plant in 1974 originally treated 3 million gallons of acid mine drainage per day (14,000 m^3/d). Initially the plant was operated 24 hours/day seven days a week but after three years the mine had been dewatered and it was necessary to operate the plant only one third of the time. At the time of the RANDOL visit the plant needs to be operated only 8 hours per week indicating that water inflow to the mine is drying up.

2. Lime neutralized sludge drawn from the mixer settles at the following rate:

Time :	0	5 min.	10 min.	15 min.	30 min.	1 hr.
Sludge height :	1000	800	680	420	280	170

3. Samples drawn from the side of the thickener indicate excellent one hour settling rates:

Sample Point :		1	2	3	4
Suspended solids :	ppm	clear	clear	20	40

4. Water from the thickener overflow used to be discharged via three settling dams to a spruit which flows via the Wilge River eventually to the Loskop Dam. Now, however, overflow water is pumped to the 93 AD army base adjacent to the old minesite for use in lavatories and as washwater. Attempts to use thickener overflow as drinking water had the army "on the trot" on account of its saturated gypsum level.

5. Sludge underflow from the thickener is pumped to a disposal dam about 4 miles away using a 60 HP Monopump. The monopump has worked exceptionally well for the duration of the operation. Thickener underflow density has never been higher than 34% solids.

6. Inspection of the sludge disposal site indicated that of the four earth dams provided for the purpose, the total amount of sludge generated to date could be accommodated in about 50% of the volume of the first dam. The dried sludge is stable and can be walked on. It takes the form of a very low density yellow cake and dries to a very low moisture content, bonedry to the touch.

7. The operator pointed out that the sludge pipe should have been constructed with flanged couplings to allow the pipe to be broken into sections when necessary to unclog it.

8. Lime consumption at full operation (10,000 m^3/day) amounted to about 750 tons per month (based on lime cost of R15,000 per month at R18-21/t).

9. Lime is purchased from Marble Hall (Pty) Ltd. If there is too much sand and grit in the lime then the lime lines clog. Lime is delivered by road tanker and conveyed pneumatically into a bin feeding a lime slaker. Conclusion: Lime with a low sand content should be selected.

10. The original plant was installed with an underground 3"Ø line to feed slaked lime slurry from the lime slaker tank to the sludge premix tank. This line was too large in diameter with the result that downhill flow velocity was too slow to keep the lime slurry in suspension. The line clogged up. The problem found a practical solution by installing a 1½"Ø flexible plastic line above ground level to transfer lime slurry to the premix tank.

11. The original plant was designed for automatic operation, but it proved more practical to operate it by manual control.

12. The plant is currently operated by one superintendent with two unskilled assistants who also preform minor maintenance tasks. Major maintenance is carried out by the New Largo Collieries mine staff.

Geomembranes manufactured by the above processes are produced in rolls approximately 1.5 m to 10 m (5 to 33 feet) in width. Geomembranes that are produced in wide rolls, typically 5 to 10 m (16 to 33 ft), and heavy geomembranes such as asphaltic geomembranes are commonly transported to the field site where they are seamed together. Geomembranes that are produced in narrow, lighter rolls are first transported to a fabrication factory where they are seamed into large blankets. Blankets can be fabricated to any designed shape and are limited only by handling weight and dimension. They are commonly less than 2000 m^2 (20,000 ft^2). Blankets are packaged and transported to the construction site where they are seamed together. Small facilities can often be lined with a single blanket, thereby eliminating the need for field seaming.

Seaming methods depend upon the composition of the geomembrane. Some geomembranes can be seamed by several different methods. The most common seaming methods for polymeric geomembranes are: (i) methods involving heat only, such as electronic (dielectric) bonding, hot air bonding, hot wedge (or knife) bonding; (ii) methods involving supply of hot base product, such as extrusion (or fusion) welding; (iii) methods involving solvents and/or cements, such as solvent bonding, bodied solvent adhesive, solvent cements, contact cements; and (iv) methods involving vulcanizing tapes or adhesives. Methods involving heat are applicable only to geomembranes made with base products sensitive to heat, ie, thermoplastics, cristalline thermoplastics and thermoplastic elastomers. All seaming methods can be used in a plant or in the field, except the dielectric method which is not used in the field because it is sensitive to dust and humidity and the equipment is cumbersome. Extrusion welding is used only for high density polyethylene. Asphaltic geomembranes are typically seamed using flame or hot wedge, with or without supply of hot liquid asphalt.

Geomembranes made in situ (ie, at the construction site) are usually continuous (ie, with no seams) and are made by spraying or otherwise placing a hot or cold viscous material onto a substrate. The geomembranes made by spraying are commonly referred to as "spray-applied geomembranes" or "spray-on geomembranes". The base product of the sprayed material is commonly asphalt, an asphalt-elastomer compound (eg, asphalt-latex, asphalt-butadiene-styrene, etc), or a polymer such as polyurethane. The sprayed material forms a continuous flexible film with little or no tack after curing. If the material is applied onto an existing surface (ie, earth or concrete) the spray-applied geomembrane is non-reinforced. If the material is applied onto a fabric or geotextile,

13. It was pointed out by Anglo American Research Laboratories that at Kromdraai the plant had excess capacity and there had proven to be more than enough available dam storage for neutralization sludges. Consequently it had never become necessary to optimize the HDS process to achieve the densest possible sludge.

14. Most of the HDS plants in the world have been constructed by Bethlehem Steel Corporation, at Bethlehem Steel installations. At ERPM the HDS plant was designed with Bethlehem Steel knowhow purchased in 1974 and subject to a secrecy agreement valid until March 1984. The Kromdraai plant demonstrates that HDS can successfully be applied based on available published information and appropriate testwork.

15. A point of interest is the high level of suspended solids in the thickener overflow of the pilot unit at Kromdraai compared with the full scale operation; the improvement believed to be due to an improved aeration device in the full scale plant.

16. No excessive scaling was observed in the Kromdraai HDS plant. Recirculation of sludges in the HDS process and the low gypsum concentrations appear to successfully avoid scale problems.

INTRODUCTION

The huge ore deposit at Phalaborwa, in the lowveld of the Eastern Transvaal is one of the world's great orebodies and mines. FOSKOR faces challenges with respect to water management and future treatment needs.

Foskor operates an open pit mine and mill to recover phosphate, copper, magnetite baddeleyite from a pyroxenite-carbonatite pipe complex.

FOSKOR also treats tailings from the adjacent operation of Palabora Mining Company after primary removal of copper by PMC to recover a phosphate concentrate.

Large amounts of water are used in the process much of which is recycled. Recycling results in a buildup of ions in the water which have an effect on the process and also on the amount of reagents required and even the selection of flotation reagents.

Environmental aspects of effluents from large flotation plants such as this are also of interest, as well as possible effluent treatment steps.

LOCATION

At Phalaborwa in the North Eastern Transvaal on the western edge of the Kruger National Park

CLIMATE

Subtropical lowveld with summer rainfall and intense heat, mild winters with no frost.

DESCRIPTION OF OPERATION

FOSKOR's mineral processing operations are summarized in the following flowchart which is straightforward.

FOSKOR processes 25,000 tpd of ore mined and stockpiled by a neighboring mine; i.e., the Palabora Mining Company and a further 25,000 tpd of tailings from this company's adjacent operations.

The basic processing steps consist of crushing and grinding followed by a sequential flotation of a copper sulfide concentrate and phosphate minerals followed by heavy mineral recovery of baddeleyite.

The second processing stream receives tailings from Palabora Mining Corporation and recovers phosphate minerals.

WATER BALANCE

The water balance is illustrated in a diagram below showing the movement of water and solids within the FOSKOR plant and tailings. Please note that this water/mass balance includes a third processing stream for treatment of ore from Foskor's own mine. This section of the plant is not currently in operation.

The macro water balance can be crudely summarized as follows:

Water Intake		Water Discharge/Loss	
Industrial Water supply	28,000 m^3/d	Discharge to Creek	39,800 m^3/d
Water in PMC tailings	22,000 m^3/d	Loss with Phosphate Conc. to Fedex	1,800 m^3/d
		Loss with Phosphate Conc. stockpiles	700 m^3/d
		Loss with magnetite Concentrate	3,400 m^3/d
		Net Evaporation and Seepage over precipitation Drainage collected	4,300 m^3/d
	50,000 m^3/d		50,000 m^3/d

WATER SOURCES

Foskor's water comes primarily from the Olifants River from which it is pumped 7 km to the plantsite at a rate of close to 30,000 m^3/d. It is used directly without treatment except settling in the Industrial Water dam.

A further 22,000 m^3/d water is received with the slurried PMC tailings which are treated by FOSKOR to recover apatite. This water contains relatively high levels of dissolved solids which comprise part of the water quality challenge.

A dam was built on the Olifants River to ensure an adequate water supply to the Phalaborwa community and industry.

WATER COST

Industrial water from the Olifants River is supplied by the Phalaborwa Water Board at a cost of a few cents per m^3.

WATER ANALYSES

Water Type	Industrial Water	Reclaimed Water I	Reclaimed Water II	PMC Feed Water	Tailings Effluent

S/S	-	-	-	-	21

EFFLUENT STREAMS

About 38,000 m^3/d of effluent is released from the FOSKOR tailings dam. Further losses of water occur through evaporation, seepage from the tailings dam and with copper and magnetite concentrates.

INTERNAL RECYCLE OF WATER

The FOSKOR operation recycles considerable quantities of water and the recycling flow pattern is relatively complicated as evident from the diagram. In addition water received with the PMC tails is a bleed from PMC's water recycling system and the effect of their recycling of water is seen on its quality.

The main recycle water loops observed in the FOSKOR flowsheet are as follows:

1) New water is added to the Industrial Water Dam which supplies water for grinding (26,000 m^3/d), 9000 m^3/d to the flotation circuit and a further 15,300 m^3/d to the magnetic separation plant. Final tailings are thickened prior to foskorite flotation, and an estimated 22,300 m^3/d thickener overflow is recycled to the Industrial Water dam.

2) Feed to the Foskorite flotation plant, i.e., underflow from thickener 7 is diluted with 12,700 m^3/d reclaimed tailings water. Finally after recovery of Baddeleyite from apatite flotation tailings they are thickened and pumped to the tailings disposal dam. A total of 84,000 m^3/d thickener overflow and 35,300 m^3/d tailings decant water is returned to the reclaim water dam with a bleedstream of 27,200 m^3/d being recycled to the baddeleyite recovery plant.

FOSKOR
MAIN WATER RECYCLING LOOPS

WATER QUALITY RELATED PHENOMENA AND PROBLEMS

1. Effect of Water Quality on Metallurgical Processing and Recovery

The water that is delivered with the PMC tails is highly contaminated with dissolved salts. Typical Analysis is as follows:

	PMC Tails Water	
pH	8.3	
TDS	5,100 ppm	
Hardness (total)	3,408	
Ca as $CaCO_3$	1,260	504 ppm Ca
Mg as $CaCO_3$	2,148	527 ppm Mg
Alkalinity (ØØ)	6	
M. O.	58	
Chloride	324	
Na	130	
K	138	
F	5.4	
P	0.2	
SO_4	3,031	

This water with combined Ca + Mg at 1031 ppm and 3000 ppm $SO_4^{=}$ has probably not reached equilibrium. The fluoride level at 5.4 is well in excess of that permitted for discharge by FOSKOR which is 1 ppm max.

The FOSKOR flotation process to treat PMC tails has been developed to be able to handle this water. Subsequent tests in which 80% of the water was replaced by "industrial water" did not result in a significant savings of reagent.

The main gangue minerals in the PMC tails feed to Foskor are calcite, dolomite, phlogopite and olivine/serpentines.

The particle size distribution of the flotation feed material is as follows:

Microns	% Mass
+425	9.2
300/425	9.8
150/300	33.3
75/150	25.0
45/75	8.4
-45	14.3

Fine feed containing apatite and calcite in contact with water that is recycled slowly adds Ca and Mg ions to the water.

The hardness of the water interferes with the froth and reacts with the fatty acid collector used to float apatite to form Ca and Mg oleates. These are insoluble soaps and have a detrimental effect on the float system.

To overcome the effect on flotation, increased amounts of gangue depressant has to be used. In the primary flotation circuit poly glycol ether is used as a gangue depressant. In the flotation plant treating PMC tails poly glycol ether plus a modified polysaccharide is used.

Several types of poly glycol ethers have been used including one manufactured by Berol Kemi of Sweden. The one found to be most suitable is a nonyl-phenol tetra glycol ether. Poly glycol ether helps to emulsify the fatty acid and may possibly adsorb on the calcite surfaces to help depress the gangue.

Chemically modified polysaccharide is supplied to FOSKOR by TROCHEM SA (Pty) Ltd.

Modified polysaccharide is manufactured from quar beans and is known as ACROL LG 21 and ACROL LG 31. Typical doses for analagous operations are 120 g per ton solids treated and a typical cost is R2.00-R2.20/Kg according to an independent source.

FOSKOR's annual consumption of flotation reagents is confidential, it is however "substantial" amounting to several million rands.

Flotation of nonmetallic minerals is discussed in the AIME-SME Gaudin Memorial Series, Volume I.

If clean water is used for flotation a carboxylic acid derivative collector such as HOECHST 3309 has been indicated to work well and economically. However, with over 5000 ppm TDS and such high hardness, the consumption of this experimental collector has been found to be excessive as it appears to be precipitated before it can get to the mineral.

Addition of waterglass Na_2SiO_3 has been found to act as a modifier/dispersant and also as a slight depressant for mica. FOSKOR uses about 600g waterglass per ton solids in their flotation reagent mix. In South Africa waterglass costs about R300/ton.

Waterglass addition is found to remove some calcium and magnesium from solution.

Considerable testwork of flotation reagents and the effects on and of ion populations in flotation pulps on flotation reagent consumption and recovery have been carried out by FOSKOR.

In the past, flotation difficulties on the main plant could sometimes be ascribed to a change in the raw water quality. The hardness of the industrial water fluctuated with the seasons reaching a peak before the first summer rains, and was shown to have an effect on apatite recovery from Foskorite ore.

The amount of suspended solids in industrial water when the Olifants River was in flood also was found to have an influence on apatite flotation both in lab tests and in the plant.

FOSKOR investigated the roles of additional ions present in flotation plant water and their interaction with ions from the flotation reagents and from the mineral constituents of pyroxenite and foskorite ore, with particular emphasis on the effects of calcium and magnesium.

Several interesting observations were made as a result of these tests:

1) Foskorite constituents, e.g., phlogopite, olivine, magnetite, calcite and apatite all contributed ions to the water phase of the flotation pulp and an alkaline pulp was obtained in each case.

2) Reagent additions to the ore pulp in dosages giving optimum apatite recovery, constantly caused a removal of ions from the aqueous phase.

3) A significant removal of silicate ions was consistently found. Soluble silicate was removed from solution by gangue minerals calcite, and iron-bearing minerals olivine, magnetite and phlogopite but not by apatite. Sodium silicate addition acts as a depressant of magnetite and olivine, and lowers the iron content of apatite concentrates.

4) Very little flotation depression of calcite was observed in the absence of apatite although in the presence of apatite the same reagent combination gave excellent apatite-calcite separation and selective depression of calcite.

5) Once the mineral mixtures had been milled and conditioned with all essential flotation reagents, the flotation water could be filtered off and be replaced by demineralized water, and the mineral subjected to flotation without any subsequent change in flotation recovery of apatite.

AFFECT OF REAGENTS & ORE ON PULP WATER QUALITY

- Foskorite ore in different stages of weathering contributes calcium and magnesium to the system and an alkaline pulp is always obtained.

- The reagents sodium hydroxide and sodium silicate soften the flotation liquid.

- Less reagents are necessary for successful flotation of apatite when demineralized water is used compared to industrial water.

- The order of addition of sodium silicate and sodium hydroxide affects the flotation recovery of apatite - soluble silicate reagent is removed from solution by the ore.

- Addition of sodium silicate and sodium hydroxide either separately or together caused a reduction in calcium and magnesium in solution in the pulps.

- Phlogopite contributes potassium, calcium, magnesium and sodium to pulp solutions.

- Addition of NaOH to several mineral slurries resulted in a drop in Ca & Mg that went into solution.

- Addition of calcium to a phlogopite slurry resulted in an increase in potassium ions in solution.

V. M. Lovell, formerly employed by the Council for Mineral Technology (MINTEK), is known to have written several papers on the effects of water quality on flotation performance of apatite from the PMC tailings. More information could possible be obtained from:

Council for Mineral Technology (MINTEK)
Private Bag X3015
Randburg 2125
South Africa
Telephone: (011) 793-3511
Contact: Librarian

Randol was unable to reach Dr. Lovell and did not have the opportunity of including his observations in this investigation.

OPTIMUM FLOTATION REAGENT COMBINATION

An optimum flotation reagent combination was found in lab tests to be as shown below. This combination gave apatite recoveries from binary apatite-mineral test mixtures exceeding 80%. All sodium silicate and caustic soda additions were made in the mill. Fatty acid (Unitol O. S. R.) and Berol E. M. U. 26 were added to the flotation pulp prior to the conditioning step.

Reagent	Reagent addition lb/ton ore	meg/l Na^+	meg/l $SiO_2^=$
Sodium Silicate	0.412	1.00	4.00
Caustic Soda	0.25	1.25	
Fatty Acid Unitol D.S.R.	0.6		
Berol E.M.U. 26	0.4		I-617

Berol E.M.U. 26 is a nonionic emulsifier of the alkylphenol poly glycol ether type, proposed as a depressant for calcite.

2. ENVIRONMENT AND EFFLUENTS

The second water problem is the discharge of effluents containing such high TDS values and in particular containing F^- at 3.9 ppm when the effluent discharge limit is 1 ppm F^-. A special dispensation from the Dept. of the Environment allows FOSKOR to discharge effluents at up to 4 ppm F^-.

According to Hendrik Best of the Dept. of the Environment, the high potassium levels in the effluents (due to contact with potassium containing carbonatites) are also toxic to fish. The water in the PMC tail slurry was reported to have 138 ppm K^+, and the reclaim water used in the plant contains around 120 ppm K^+.

This is the one and only reference found during this investigation to the possible toxicity of potassium to fish. This point has been queried for confirmation from:

Hendrik J. Best
Department of the Environment
Private Bag X313
Pretoria 0001

Telephone: (012) 268-402

It is interesting that even though phosphate minerals are one of the principle values recovered by FOSKOR, phosphate levels in recycled water remain well below 1 ppm.

3. SCALE AND CORROSION

Although the recycled water at FOSKOR is very high in Ca^{++}, Mg^{++} and $SO_4^=$, it is not found to cause scaling nor corrosion in the plant. No scale inhibitors are used. The reason that such a high Ca^{2+} and $SO_4^=$ can be in solution without scale problems seems to be the presence of Mg^{2+} which seems to modify the gypsum solubility.

4. PMC ACID SCRUBBING EFFECTS

In the adjoining PMC plant water is recycled and total dissolved solids build up more than they do in the FOSKOR plant mainly because of their SO_2 gas scrubbing operation. Final tailings material is subjected to classification. The fines fraction is then used for gas scrubbing. Calcite/dolomite reacts with undissolved SO_2/SO_3 gas resulting in high concentrations of Ca^{++}, Mg^{++} and $SO_4^=$ ions in the water phase.

It has been speculated by independent sources that water that has passed through the gas scrubber results in improved flotation recovery of valerlite, a copper mineral. This was not confirmed but is possible since SO_2 can convert oxidized copper to metallic copper which may float better.

WATER CONSUMPTION

Net water consumption at FOSKOR is complicated by the additional water that enters the processing system with the PMC feed stream. Examining the treatment of ore mined by FOSKOR in a separate circuit, it appears that net fresh water consumption works out to 26,700 m^3/d to treat 25,000 tpd ore or about 1.07 m^3 water/ton ore.

TAILINGS DAM DESIGN

FOSKOR employs a consulting firm on a retainer to review water management and for engineering aspects of their tailings disposal including dam design.

2. Feldspar Six 2 4 m x 3 6 m rod mills in closed circuit with a twelve cone classifier for each mill

Copper Flotation:

1. Feldspar Copper flotation is done in 24 8 4 m flotation cells by means of rougher and cleaner stages. The copper concentrate is stockpiled for subsequent despatch to PMC for refining under contract

Magnetic separation:

1. Feldspar After copper flotation the magnetite is extracted by means of magnetic separators and pumped to stockpiles for possible future use. The non-magnetic fraction is pumped to the phosphate flotation plant for flotation of phosphate concentrate

Phosphate flotation:

1. Pyrosmite The pulp from the mills is treated with reagents prior to phosphate flotation. Flotation is carried out in 88 8 678 m³ flotation cells through four stages namely rougher, scavenger, cleaner and re-cleaner
2. Feldspar Prior to phosphate flotation the non-magnetic pulp from the magnetic separators is treated with reagents. The phosphate is then floated in 32 8 678 m³ flotation cells through the same stages as for pyrosmite
3. PMC tailings The phosphate is floated with a combination of reagents in 48 8 4 m³ and 288 1 416 m³ flotation cells through the same stages as already mentioned

Filtering:

1. Feldspar The phosphate concentrates from the pyrosmite flotation and PMC tailings flotations are partly dewatered through a succession of thickeners and disc filters to a moisture content of 10%. After filtration concentrates are removed by a conveyor belt system to stockpiles

Storage of Concentrates:

320 000 tonnes with phosphate concentrates can be stored in two bunkers and open stockpiles from where it is reclaimed for drying

Drying:

The phosphate concentrates are dried by means of three 21 m rotary kilns and two fluid bed dryers to a moisture content of approximately 1% and despatched to consumers

Heavy Minerals Plant:

1. After phosphate flotation the tailings are pumped to the heavy minerals plant where baddeleyite is recovered by means of gravity and leaching
   Baddeleyite concentrates are exported

INTRODUCTION

Inclusion of a discussion of a sewage works in an investigation of water management and water treatment for mining and metallurgical operations is of particular interest because reuse of treated sewage water represents a major potential addition to water that is available for metallurgical processing.

Treated sewage water is used in several gold plants, after being added to the tailings dam to blend with other reclaim water at, for example, Vaal Reefs and at Deelkraal. At Kloof Gold Mining Company and West Drefontein (both Gold Fields of South Africa) reclaimed sewage water is being considered for use in underground refrigeration units. At President Brand treated sewage water is believed to have had detrimental effects on flotation recoveries and on carbon adsorption performance. At Vaal Reefs, treated sewage effluent is used without problems in gold and uranium recovery circuits.

At Hartebeesfontein Gold Mining Company (Anglovaal) laboratory tests showed that treated sewage water from the new Stilfontein Sewage plant could be used for high pH flotation of pyrite and gold, whereas water samples from the old Stilfontein Sewage Treatment Plant showed a negative impact on recovery.

The purpose of a visit to Stilfontein was to find out what the differences in treatment process between the Old and New Stilfontein Sewage Treatment plants are and also what differences in water quality between the products of these two plants could account for the different test results reported by Anglo-Vaal Research Laboratories.

STILFONTIEN SEWAGE TREATMENT PLANT

A visit to Stilfontein Municipality failed to find any knowledgeable engineer who was familiar with the sewage treatment technologies employed. Eventually the retired former municipal engineer was located and he advised that there are in fact three sewage treatment units.

1) The old biofilter plant
2) The new biofilter plant
3) The new activated sludge plant

RANDOL was referred to a firm of consulting water treatment engineers in Johannesburg that is responsible for quality control checks and for civil engineering and process advice.

Contact Philip J. Pybus

It was revealed that the "Old" plant at Stilfontein is a biofilter plant and the "New" plant is a Mark III 5-stage Badenpho activated sludge plant designed in 1977 based on CSIR technology. Incoming sewage water was split on entering the property and would be of essentially the same quality to both sewage plants.

"OLD" PLANT

The old plant using biological filtration to remove organics is overloaded and not performing well according to the consultants.

BIOFILTER SEWAGE TREATMENT

Biofiltration is one of the oldest most established and operator proof sewage treatment processes. Biofiltration uses trickle filters with a high surface area substrate on which the bacteria attach themselves, and is effective for removal of organic materials. However, biofiltration does not come close to meeting modern day PO_4^{3-} and NH_3 removal requirements. For example, in many parts of South Africa a maximum of 1 ppm $PO_4^{=}$ is allowed to avoid utrification of dams. In parts of the USA, e.g., Reno/Sparks the limit is 0.5 ppm for total P. Most phosphorous in effluents is in the form of orthophosphate $PO_4^{=}$ except that bound in cell biomass.

NEW BADENPHO PLANT

The "New" Stilfontein Sewage plant is a Mark III Badenpho plant designed by the CSIR in 1977.

The Badenpho process was developed by the CSIR and more information on the process can be obtained from:

National Institute for Water Research
CSIR
P. O. Box 395
Pretoria 0001

Telephone: (012) 86-9211
Contacts: Andre Gerber Biotechnology Division

in effluents the ratio of nutrients may not be the same as that required by the microorganisms. The aim of the Badenpho (and later Phoredox process) is to trick the bacteria into removing more phosphate than they really need. In the Phoredox process bacteria take up to 10 times the amount of phosphate needed for their metabolism.

Although it is now known how to make the process work, the pathways and mechanisms of "luxury" phosphate uptake have not yet been sorted out, and is the subject of further research.

NH_3 must be removed from recycled sewage water because it stimulates aquatic plant growth and results in an oxygen deficiency in the water. Also where the water is to be used underground in South African mines, it must be rendered potable and for each 1 ppm NH_3, 10 ppm Cl_2 are consumed during chlorination, so it becomes important to remove as much ammonia as possible.

The bacterial processes employed in Badenpho activated sludge processes are:

1) NH_3 oxidation by bacteria to NO_3^-
2) PO_4^{-3} removal in luxury amounts by bacteria
3) NO_3^- denitrification and discharge to air as N_2

In earlier denitrifying processes used in the USA, NO_3^- conversion to N_2 is achieved by adding methane as a carbon source for the bacteria. In the Badenpho and Phoredox processes, this is achieved using the carbon in sewage to provide the energy needed by the bacteria instead of methane.

The 5 stage Phoredox process consists of the following steps:

1. ANAEROBIC DIGESTION Anaerobic microorganisms are introduced in recycled sludges from the final clarifier. The incoming feed is rich in organics, ammonia and phosphates.

2. ANOXIC DENITRIFICATION Sludge is recycled to the primary aerator from the next stage. This step removes most of the NO_3^-. The rich organics provide energy to convert NO_3^- to nitrogen.

3. PRIMARY AERATOR This step oxidizes ammonia to NO_3^- and also results in some PO_4^{3-} uptake. Waste sludge is bled from this stage containing PO_4^{-3} as polyphosphate. Sludges are also recycled to the previous stage.

4. SECONDARY ANOXIC REACTOR This step gets rid of the remaining NO_3^- and consumes nutrients provided by the dying organisms and any residual organic matter.

5. SECONDARY AERATOR Stages 4 and 5 are a polishing step.

6. CLARIFIER The clarifier sludge containing aerobic microorganisms is recycled to the primary anaerobic stage.

In the Badenpho/Phoredox process the recycled sludge serves as an innoculant and affects the degree of stress on the bacteria in the anaerobic stage.

The Badenpho process generates sludges with up to 15-30% P content. It is not yet known how to dispose of these sludges. It may be possible to condition the sludge with lime and ferric chloride and use it as a soil conditioner. More work is needed in this area.

The Badenpho and Phoredox patent is owned by S. A. Inventions Development Corporation, and licenses can be purchased through:

Meiring & Partners, Inc.
Pretoria

Commercial scale Badenpho plants are installed in South Africa, Windhoek, Brazil, Canada and the USA. The US experience is at South Lake Tahoe Water Works where Culp & Culp Brothers have acted as consultants on the process.

STILFONTEIN TREATED WATER QUALITY

The following analyses of product from the "new" activated sludge plant and the "old" biofilter plant taken on five different days from midwinter to early summer indicate the variation in quality that can be experienced in this water.

THE 5 STAGE BADENPHO PROCESS

AMMONIA IN
TREATED SEWAGE WATER

CHEMICAL OXYGEN DEMAND IN
TREATED SEWAGE WATER

CONCLUSIONS

1. There is an indication that the Badenpho process yields a water product from sewage that can be used in high pH flotation without adversely affecting recovery - based on tests by Anglo-Vaal Research Laboratories.

2. The Badenpho process is designed to remove NH_3, NO_3^- and PO_4^{-3}, however according to Stewart, Sviridov & Oliver, and as indicated by the Stilfontein plant results, PO_4^{-3} removal does not achieve the 1 ppm target claimed, and no comparative data were reported for PO_4^{3-} removal by the biofiltration plant.

3. If Stilfontein is a typical sewage treatment operating environment, then such operations are subject to wide performance fluctuations and relatively primitive operating controls.

4. When drawing water samples for flotation tests from biological sewage treatment plants it is important to analyze the water samples used to characterize its quality. Although the results are encouraging it remains to determine whether flotation results will remain as good through the full range of water quality fluctuations experienced in the Badenpho activated sludge water product.

5. Although the Badenpho process treated water has been found to be suitable for use in high pH flotation of pyrite and gold from Witwatersrand ores, the reasons for the improved performance using this water compared with biofiltration are not understood. More research is needed to be able to use this water with confidence and to understand what water quality parameters are important.

6. Consideration can be also given to using RBC's for removal of NH_3 from treated sewage water for use as recycle water in underground refrigeration.

7. The use of treated sewage water in metallurgical operations, especially flotation plants, is highly contraversial. Gencor and President Brand claim that it causes a reduced recovery. Other plants use treated sewage water in gold recovery (Vaal Reefs and E. Driefontein), and others have shown on a lab scale that if treated by the activated sludge process, it can be used for flotation.

   At Cons. Murchison recycled sewage was formerly used for flotation, but has since been discontinued.

   Elsewhere, Kloof G. M. Co. Ltd. is seeking ways to use treated sewage reclaim water in underground cooling of their stopes.

President Brand G. M. Co. Ltd. has found that after sewage water is used as a coolant in the Peabody Scrubber, then it can be used in flotation without deleterious effects.

8. The performance of the Badenpho and Phoredox Process to remove NH_3, PO_4^{-3} and NO_3^- from sewage water is also contraversial especially for remote locations.

DATE OF VISIT	February 1984	

INTRODUCTION

During the severe drought conditions of 1982-4 in the Transvaal it became urgently necessary to reduce water consumption by the mines and metallurgical complex. This resulted in the need to recycle more water. Increased water recycling combined with a general deterioration of water quality led to a buildup of TDS which had an impact on metallurgical recovery, corrosion, etc.

Rustenburg Platinum Mines and Rustenburg Refiners undertook an extensive program over an 18 month period to overcome water related problems. At the time of the RANDOL visit, a comprehensive and innovative systems approach was being implemented, from

BASIC PLATINUM TREATMENT PROCESS

which much can be learned. The Rustenburg water management program is an example of the steps that must be taken when drought affects an area. The Rustenburg water management plan is one of the most advanced, if not the most advanced encountered in South Africa for a mining operation.

Platinum mining and recovery processes are considered proprietory and company confidential and this investigation therefore deliberately ignores process details. This was a regretable necessity since in order to fully appreciate the systems approach adopted at Rustenburg, and to see how a change of water quality at one end of the process has an impact at another end of the plant, it would be helpful to have a somewhat detailed understanding of the various processing steps. Nonetheless, even without getting into process details it is possible to gain picture of some of the principles of an advanced water management program.

The focus of this report is therefore on the water management and treatment aspects as they might be applied to almost any hydrometallurgical operation and mine-mill complex.

RANDOL did not ask questions as to how platinum is extracted or refined. A general knowledge rough idea of the process is provided below, but it may be completely incorrect and misleading. It only provides a hypothetical framework within which to discuss water management and treatment steps.

Information released by Rustenburg Refiners Ltd. has had to be rather general.

Items of particular interest at Rustenburg Refiners Ltd. and Rustenburg Platinum Mines Ltd. are:

- Overall salt balance control in recirculated water system.
- Treatment of minewater with 5000 ppm TDS to make a usable domestic potable water
- Affect of water quality on flotation recovery.
- Pretreatment of "fresh" feedwater to reduce the amount of chloride buildup in the plant due to recycling.
- Segregation of high chloride effluents so that only a relatively small volume of water requires desalination, not the complete water inventory.
- Use of R. O. installed to recover water from boiler blowdown and demineralization ion exchange concentrates etc. Operating problems experienced in the use of R. O. for this purpose.
- Proposed use of seeded slurry evaporation to recover water from concentrated effluents.
- Effects of high TDS buildup in minewater on flotation recovery.

BASIC METALLURGICAL TREATMENT PROCESS

Ore is crushed and ground and a concentrate containing all the metal values recovered by flotation, after recovery of any PGM metallics by gravity concentration.

The concentrate is matte smelted. The matte is cooled, then crushed and separated magnetically to yield most of the PGM values in a magnetic alloy. The non magnetic fraction contains Ni, Co and Cu values which are leached sequentially followed by smelting of the leach residue.

In reality the process is very much more complex than this involving pressure leaching in autoclaves and ion exchange separation of cobalt from nickel sulfates. From a water management standpoint it is adequate to know that the process involves a combination of pyrometallurgical and advanced hydrometallurgical leaching and precipitation steps.

Rustenburg Platinum Mines and Rustenburg Refiners' metallurgical facilities are spread over several operating units. There are several separate mining operations some of which have associated milling and flotation plants. Concentrate is shipped by rail to the central matte smelter.

There are two "wet" metallurgical plants that treat the matte smelter products. One of these treats the magnetic PGM concentrate recovered from the crushed matte, the second is a base metal treatment plant that makes Ni, Cu, Co and Na_2SO_4 byproducts from the non magnetic fraction of the ground matte, yielding some incremental PGM values.

Both metallurgical plants treating the matte use fresh water. The new base metal recovery plant which is primarily a nickel refinery was commissioned in 1982 and consumes an order of magnitude more water than the platinum recovery plant.

MAIN AIMS OF WATER MANAGEMENT/TREATMENT PROGRAM

1. To reduce net water intakes
2. To overcome corrosion problems associated with rising chloride levels in feedwater from RWB
3. To achieve zero discharge status by treating effluents and recovering usable water

ZERO DISCHARGE

Rustenburg Refiners is now operated as a zero discharge site. All available water is recovered for recycling. The site has a net evaporation climate.

Rather than build larger evaporation ponds, the water balance has been closed by installing R. O. and by using mechanical evaporation capacity which helps by removing dissolved salts from the system and returning usable water.

WATER SOURCES

The Rand Water Board supplies water to Rustenburg Platinum Mines and Rustenburg Refiners. This water, however, is not the sole source. There is some water from sources other than that used on the Witwatersrand, i.e., from the Boskop Dam, Hartebeespoortdam, Vaalkop Dam and some underground springs.

Rainfall at the Rustenburg site has averaged 627 mm for the last 25 years, and occurs mainly during November to January. Three lined ponds with about 12,000 m^3 capacity contain collected rainwater runoff. This water is returned to the process water system.

Other major sources of water to the mines and mills include underground minewater and treated municipal sewage effluents.

Rand Water Board water was priced at R0.182/m^3 as delivered to Rustenburg Platinum Mines. Normally RWB from the Vaaldam is delivered to Rustenburg Refiners however, during the drought emergency water from another dam - the Bospoort Dam - was being blended into the supply. Bospoort water had a higher TDS and chloride level. The plant requested that only RWB water be delivered, however no sooner had this been achieved than the quality of RWB water deteriorated to 70 ppm Cl^-. There had been an improvement to 30 ppm Cl^- in the RWB water at the time of the Randol visit in February 1984. Bospoort water blended with RWB feedwater had resulted in 150-200 ppm Cl^- in water supplied to the metallurgical plant.

WATER REQUIREMENTS

1. Flotation Plants

   Water for flotation plants is obtained from local sources notably wellwater and underground minewater.

2. Mineworker Hostels require about 2000 m^3/d of potable water.

3. Metallurgical Process Water

PGM Plant	50 - 60	m^3/d
Base Metal Plant	5 - 600	m^3/d
Steam Condensate	150 - 200	m^3/d
Demineralized Water	100	m^3/d
TOTAL	900	m^3/d

The metallurgical process water needs were formerly supplied by Rand Water Board, but is now drawn from the process water recycling loop.

Water Losses

There are three main water losses from the metallurgical processes:

- Evaporation from the base metal plant processing 450 m^3/d
- Balance to Na_2SO_4 crystallization plant also lost by evaporation 250 m^3/d
- Utility area wastewaters 200 m^3/d

About 50% of the evaporated water from the Na_2SO_4 crystallization plant is recovered and returned to the process water system as a very good quality low TDS water at 20-30 uS/cm.

MATERIALS OF CONSTRUCTION

The new base metal plant equipment is constructed mainly from 316L stainless steel.

The new evaporation desalination plant will have titanium tubes and stainless steel 316L sumps.

WATER BALANCE

A key part of the success of Rustenburg Refiners water management program has been their ability to precisely define the water balance for the complex metallurgical facility as a whole, and for each unit operation, without which it would be impossible to design or implement a plan.

The water balance for December 1983 with average figures for the previous six months is shown in the figure as an example of what such a balance looks like. Note the relatively large percentage of process water that is used for utilities.

WASTE STREAMS

1. Utilities water effluents
2. Rainwater runoff from base metal plant site
3. Rainwater runoff from Na_2SO_4 crystallizer site
4. Accumulated effluents in evaporation dams

A processing scheme has been devised to segregate the various waste streams for treatment and recycling of recovered water.

WATER QUALITY EFFECTS

1. Especially during the dry season water available to the flotation plants increases in hardness as Calcium and magnesium levels increase. There have been several studies to examine the effects of this hardness on flotation recovery. Some indicate a decrease in recovery of 0.5-1.0% or so but other tests were unable to confirm this. No data was obtained.

2. Some years ago the sodium sulfate crystallizer plant was owned and operated by an independent contractor prior to the recent acquisition of the plant by Rustenburg Refiners. There has been some mention of Na_2SO_4 in water seeping into the underground workings and interacting with pyroxenite rocks to result in high Mg concentrations in minewater which, it is said, had a negative impact on flotation recovery. This phenomenon was not confirmed, but it was clearly stated that current practice avoids any possibility of Na_2SO_4 in seepage losses.

3. The new base metal recovery plant is constructed from 316L stainless steel. Increased chloride levels in the RWB water used in the plant are reflected in a generally higher concentration of chloride in the process due to in-plant evaporation. New water enters in the copper leach circuit and exits at the nickel circuit during which there is a 200% increase in the salt load. Hence 70 ppm chloride becomes 140 ppm chloride in the nickel circuit if RWB water is used, and more if Bospoort water is used.

   Pitting corrosion was observed in the pressurized leaching equipment and a couple of vessels had to be replaced.

   For this reason it is very important that high chloride levels in feedwater to the plant be avoided. An area of major concern is the future quality of incoming water, particularly with respect to chloride content.

WATER TREATMENT AND RECOVERY PROCESSES AND EFFECTS

1. Sodium Sulphate Crystallizer

   Concentrate leach solutions after recovery of base metals Ni, Cu, Co are acidic and contain high levels of sulfuric acid, which is neutralized by NaOH and then evaporated to remove Na_2SO_4 as a dry product.

   Some 50% of the evaporated water from Na_2SO_4 crystallization is recovered and returned to the process water system. This water is usually of excellent quality with a conductivity of 20-30 uS/cm.

There are occasional deviations but no precautionary measures are taken except for an alarm system which sounds whenever conductivity exceeds 100 uS/cm at which point the flow is automatically diverted.

Until recently the condensate conductivity was much higher due to sulphate content which was solved through repair to the evaporators.

The Na_2SO_4 crystallizer plant has adequate capacity to handle the total flow of solution from the base metal plant which was operating below capacity.

The excess evaporator capacity was being used on a short term basis to treat effluent water that had accumulated in a pond for several years. This water was treated by a lime/soda softening plant ahead of evaporation.

The Na_2SO_4 crystallizer plant was being used to treat the following solutions to yield dry solid salts and water which is returned to the process water circuit:

- Na_2SO_4 solution from base metal plant
- Runoff from the Na_2SO_4 plantsite
- Water recovery from the waste effluent ponds after lime/soda treatment and filtration

Prior to the Na_2SO_4 crystallizer operation being acquired by Rustenburg Refinery, the condensate was lost. Now it is recycled as process water.

The Na_2SO_4 crystallizer plant consists of a 3-stage multi-effect evaporator followed by a centrifuge and air drier to produce a dry solids product.

2. Utility Water Effluent Treatment

Effluents are derived from the utility water system which yield the following effluents:

Water softening IX regeneration liquors	40 m^3/d
Demineralizer regeneration liquors	30 m^3/d
Cooling tower blowdown	20 m^3/d
Boiler blowdown	35 m^3/d
Boiler ash conveying water	10 m^3/d
Total at current production	135 m^3/d

The above effluents had been accumulating in lined evaporation ponds which at the average 760 mm/year net evaporation rate were able to lose an average of 110 m^3 water/day.

The short term answer has been to use temporary Na_2SO_4 crystallizer capacity to evaporate the accumulated excess effluents. The medium term objective is to install evaporator capacity to treat all effluents when the base metal plant is running at full capacity and the Na_2SO_4 crystallizer capacity is needed for that stream.

Resource Conservation International, a South African subsidairy of Resources Conservation Company was consulted to design a short term and a long term plan to conserve water and to avoid any effluents, on the basis of which it has been decided to install an evaporator plant to treat all wastewater arisings.

The old base metal recovery plant used to generate a gypsum effluent which sometimes contained base metal values. This has been avoided in the new base metal plant.

EFFLUENT DAM COMPOSITION

The liquor contains 12,000 ppm Na_2SO_4 with $CaSO_4$ at 95% of saturation. TDS is about 17,000 ppm and Ca concentration is about 600 ppm. The effluent pond water also contains 300 ppm Ni and some Mg.

The effluent dams were lined with Gundle Plastic about ten years ago. The dams are to be emptied and the plastic may be replaced. Activated bentonite will also be considered a replacement lining.

EFFLUENT POND: PROPOSED PROCESS

It had been proposed to treat the effluent pondwater by adding 120% of the stoichiometric dose of lime and soda ash in sequence in separate tanks with 1½ hours residence time each to achieve a lime-soda softening followed by clarification to settle out precipitated $Ni(OH)_2$, $Mg(OH)_2$ and $Ca(OH)_2$.

In the process pH would be adjusted from incoming feed at pH 7.5-8.5 to pH 10.5 by lime addition followed by soda ash addition to pH 11-11.5.

The thickener underflow would be dewatered by rotary drum filter with the filtrate and clarifier overflow advancing to the Na_2SO_4 crystallizer.

The above lime-soda softening would drop calcium to less than 5 ppm and nickel to less than 3 ppm when working well.

The conversion of the old base metal treatment plant to the above use was achieved to handle 20 m^3/h maximum throughput with clarification to less than 50 ppm S/S.

Through the use of lime for precipitation the settled solids are much denser than if NaOH were to be used, although NaOH is found in tests to give a clearer overflow but a slower settling sludge.

The total cost of this treatment process worked out to R1.50/m^3 with a credit for the nickel values in the precipitate making it possible to recover some of this cost.

EFFLUENT TREATMENT PLANT

Conclusions

1) Lime-Soda softening as a means of reclaiming process water is far from inexpensive.

2) Once the base metal refinery is back in full production the Na_2SO_4 crystallizer capacity will be needed for plant effluent and no extra capacity will be available for effluent treatment.

3) In the base metal plant chloride is converted to chlorine in the electrolyte tankhouse which results in a drop in chloride level in the electrolyte and about 5 ppm Cl_2 in the gas above the cells which is vented using forced air circulation to disperse the Cl_2.

This bleed of Cl^- from the system prevents NaCl from building up in the Na_2SO_4 crystallizer circuit.

4. Desalination R. O. - Utility Effluents

A reverse osmosis plant has been installed to treat some of the effluent water streams instead of pumping them to the effluent pond. A relatively small R. O. unit using spiralwound membrane modules was supplied and installed by:

Cass Africa (Pty) Ltd.
P. O. Box 51051
Randburg 2125

Telephone: (011) 789-2908
Contacts: Tom deLange

Only those effluents which are compatible with R. O. are being treated:

1) Boiler blowdown
2) Cooling tower blowdown
3) Low salinity (less than 4000 uS/cm) end of the demin plant regeneration selected by a conductivity meter activated valve.

In February 1984 the R. O. installation was being commissioned in this application - not without startup problems due to potential fouling of the membrane. More information may be available by now on the ultimate performance of the R. O. plant for treatment of utility wastes from Rustenburg Refiners or from Cass Africa.

Description of R. O. Plant

A combination of the effluent streams listed above is mixed in a 63m^3 sump located near the utilities section of the plant.

Step 1 These solutions at pH 9 are recirculated constantly to provide good mixing.

Step 2 The mixed feedwater is next settled in a 140 m^3 settling dam to cool the blowdown effluent to below 35° C which is the maximum tolerable by the R. O. membrane. Cooled effluent next passes via a 4 m^3 tank at pH 8.5.

Step 3 Next is pretreatment of R. O. feed including acidification to pH 5.6. If alum is used for coagulation then the pH must be below pH 6.5. Purpose of acidification is to convert carbonate to bicarbonate to avoid scale fouling of the membrane.

Step 4 Dechlorination by 5 ppm Na_2SO_3 addition.

Step 5 Coagulation. Alum has been tested as a coagulant and found to work. Because of dispersants in the cooling tower a dose of 100 ppm alum is needed. RANDOL suggested the use of activated bentonite and an anionic polyelectrolyte at B and organopol at C.

Step 6 Sand filtration to yield a filtrate with zero measurable suspended solids or less than 1 ntu.

Step 7 Addition of 4 ppm Flocon 100 scale inhibitor supplies by Pfizor Chemicals.

Step 8 Cartridge Filtration using a polypropylene 5 micron filterite cartridge supplied by Chemilite.

Step 8 Feed to R. O. modules via Tonkflo 27 stage centrifugal pumps supplied by Tonkflo Corp., Minneapolis, Minnesota.

Step 8 R. O. System consisting of two systems each using 3 modules. Each stream is capable of 70 m^3/d. UOP 4600 pA modules were installed in February. These were thin film polyamide composite membranes which are chlorine sensitive.

R. O. Feedwater Quality:

TDS	1,500 ppm
Ca	75 ppm
Cl^-	200 ppm

R. O. Performance

80% Recovery of water was possible in theory from this feedwater before gypsum scaling would occur, allowing a safety margin.

Conclusions:

1. The number of pretreatment steps to be attended to in treating water of this kind by R. O. makes the overall system complicated.
2. Recovery even from relatively low TDS water with low calcium is only 80%.
3. Even with the pretreatment steps, problems were experienced in removing foulants ahead of R. O.
4. This application appears to be suitable for seeded slurry reverse osmosis.

5. Desalination R. O. Feedwater

Because one of the problems experienced as a result of water recycling and deteriorating feedwater quality has been chloride corrosion, Rustenburg Refiners was considering the installation of a R. O. plant to treat feedwater as an alternative to the brine concentrator. No details were available and at the time of the RANDOL visit, no order had yet been placed for such an R. O. plant.

6. Demineralization

Rustenburg Refiners produce about 340 m^3/d demineralized water using ion exchange. This plant yields about 20-40 m^3/d of regen solution. One of the purposes of the new small R. O. plant mentioned above was to remove the contained salts.

7. Brine Concentrator

Rustenburg Refiners had set the objective of emptying the existing effluent dams and then to treat collected runoff water.

Tenders had been called for an evaporation plant of 240 m^3/d capacity.

The proposed process was to adjust pH to 6.0 to control corrosion and to keep all carbonate in the non-scaling bicarbonate form.

The brine evaporator was to be constructed with titanium HE tubes. The sump was to be stainless 316L.

The effluent dam contains about 40 ppm SiO_2 and almost saturated $CaSO_4$. The limiting factor on concentration was Na_2SO_4 crystallization in the concentrate. It was proposed to use a seeded slurry process such as that installed at several plants in the USA by:

Resource Conservation Company
3101 NE Northrup Way
Bellevue, WA 98004

Telephone: (206) 828-2400
Telex: 350-160
Contact: Russel Vandenberg

Resource Conservation Company International
P. O. Box 47041
Parklands 2121
South Africa

Telephone: (011) 788-5070

Evaporation desalination plants and equipment are discussed in a separate chapter of this report. Although Resources Conservation Company International have installed more of seeded slurry evaporators than anyone else, their tender for this installation was significantly more expensive than the other tenderers of falling film, vertical tube vapor compression evaporators. Six companies tendered evaporators for this job including more than one offering seeded slurry evaporation.

The Rustenburg seeded slurry evaporator will have a recovery of 95% at less than 10 ppm TDS.

Capital cost order of magnitude for this installation works out at R4000 per m^3/d capacity or around R1 million for a 250 m^3/d plant. One of the suppliers offered a plant for R1.8 million which indicates the wide range in cost of these plants. Several suppliers of evaporator desalination plants are listed in the chapter on the subject. This plant had been commissioned by the end of 1984.

8. Potable Water

Rustenburg Platinum Mines has set a target of becoming self sufficient in potable water for the semi-skilled labor hostels at the mine. Water available from underground includes two mine service water sources with 5000 ppm TDS and 93% $CaSO_4$ saturation i.e., around 2000 ppm.

The process selected to make this water potable is as follows:

Lime/Soda softening

↓

Clarification

↓

Chlorination

↓

Sand filtration

(Conventional downflow)

↓

INTRODUCTION

Diamond recovery technology details are proprietory so only the most general information was released by Debeers. Diamonds are often found in areas where water is in short supply so water recovery and management is an important aspect of the feasibility of several projects.

Diamond recovery is by physical processes. The ore is relatively coarsely crushed and screened to liberate diamonds up to ¼ inch in size so it would be expected at first that water recovery would be an easy task, but it is not. The problem is that Kimberlite ores contain a large percentage of ultra fine minus 1-micron ultrabasic particles which, similar to phosphate slimes in Florida, simply do not want to settle out.

Points of interest in this trip report include:

1. A statement of the problem. If a low cost answer could be found to water recovery from Kimberlite slimes, this would be of significant interest to diamond mines.

2. There is room for improvement in water management in diamond mines that requires upgraded technology.
   - Reduced flocculant costs
   - Higher density thickener underflow
   - Reduced pumping costs
   - Availability of water

3. A highly innovative but simple use of poor quality decant water to prewash crushed ore has made it possible to reduce flocculant consumption substantially.

KIMBERLITES

There are 39 different types of Kimberlite. Most Kimberlite contains large quantities of a weathered product called Saponite which is a fine clay. The Kimberlite slimes are high in calcium and magnesium. Kimberlite slimes raise the pH of water in which they come into contact to around 9.0-9.5.

COST OF WATER

Water is drawn from a dam below Bronkhorstspruit 40 km to the east. The only cost is for pumping which amounts to around R0.07/m^3. However, the development of a new African Homeland for the Kwa N'debele may result in a competing need for water during the remaining life of the mine, which is about 50 years. Despite a major search no alternate water sources have been found.

OPERATING COSTS

Diamond mines treat large volumes of feed to recover a relatively small volume of product. Treatment costs must be kept low and are said to be much lower than for gold-uranium recovery operations. Debeers claims that their diamond mines are more conscious of water that other mining industries.

The principal operating cost components of a Kimberlite processing plant are:

Water	
Power	
Reagents :	Flocculants
	FeSi HMS Media
Labor	

WATER PROBLEM/CHALLENGE

The main problem with water is that it is not generally available in the desired quantities, so it must be reclaimed from the tailings. However, slimes which are abundant in Kimberlites are of such a nature that only about 25% of the water contained in slimes sent to the slimes dams can be reclaimed.

Slimes on thickening historically never gave an overflow with better than 8-9% solids. Through improved flocculant development, Premier Mine now achieves 1-2% solids in the overflow which they "can live with" comfortably.

GENERALISED FLOWSHEET FOR DIAMOND RECOVERY

Attention has been focused acutely on water supply and on conservation of water as a result of the 1982-4 drought. Water resources are subject to reallocation which could deprive some mines of their traditional supply as an emergency measure and in other mining operations there simply is not enough water for a large mine and concentrator to operate without recycling.

GENERALIZED RECOVERY PROCESS

Premier Diamond Mine uses dry crushing which allows improved control of water management. Dust is controlled using a scrubbing system which consumes water to wet down the dust that is collected. Generally gyratory crushers are preferred because they break less diamonds than jaw crushers.

After crushing the ore is washed and scrubbed using 0.4-1.0 m^3 new water per ton ore in addition to the overflow recovered from the thickener at 1-2% suspended solids which is recycled to the scrubber.

At Premier Telsmith scrubbers are installed and a 100' Ø thickener yields 3000 m^3/h overflow water.

After scrubbing the ore is screened to separate it into several size fractions. The minus 1 mm fraction is sent to the thickener. Underflow at 35% solids is pumped to a slimes dam and overflow is returned to the scrubber with 1-2% moisture.

The scrubbed, screened and sized ore is next concentrated by Heavy Media Separation HMS using ferrosilicon. The density of diamonds is 3.5 compared with the gangue at 2.7.

Finally the HM plant concentrate is further concentrated across grease belts or by X-ray fluorescence ore sorters.

At Premier Diamond Mine the main plant has two 100' Ø thickeners for slimes water reclamation. However, a second plant is installed for secondary recovery of diamonds from older tailings which also employs two 100' Ø thickeners.

The thickener underflow is pumped to the slimes dam at 35% solids and decant solution with about 12% solids is used to dilute the thickener underflow to reduce their viscosity for pumping to the dam. Some of the 12% solids decant water is used for a prewash scrubbing step. The slimes dam is located 4 Km downhill from the plant and flow must be kept at 3m/s downhill to prevent coarse solids from settling and 2m/s for the uphill flow.

The slimes dam at Premier is 300 hectares in size and is covered by water running 12% solids. The site has very high humidity and is hot. If a mine manages to reclaim 40% of the water sent to the slimes dam it is doing very well indeed - or it may be putting too much water in the slimes dam in the first place.

WATER CONSERVATION IDEAS

- Since 25% of the ore ends up as slimes which are responsible for a major part of the water loss from the plant, one way to reduce water consumption is to reduce the amount of slimes.

- For planning purposes the net water requirements are equal to the weight of slimes generated.

- Hence less water will be required if it is possible either to reclaim more water from the slimes dam or if a way can be found to generate less slimes in the first place.

A SYSTEMS APPROACH

1. Examining a schematic for a hypothetical diamond recovery plant treating 10,000 tpd ore, the water flow will be as shown in the diagram below

GENERALISED WATER FLOW CHART

2. Selection of Dry/Wet crushing

ROM ore is tipped directly into a large gyratory crusher and reduced to minus 6". Primary crushed ore on a large conical stockpile with 3 draw points works well during 8 dry months, except for lots of dust. However, during the 4 wet months ore hangs up in the stockpile. Most diamond plants are designed for the worst conditions, i.e., the wet months, and operated that way yearround.

If water supply really becomes critical, then a dual process has been proposed which would operate dry during the dry months and wet during the rainy months.

In using the above scheme, as much as possible of the minus 1 mm particles would be separated dry for disposal by a water efficient agglomeration process. Only when the secondary crushers clog in the wet months would the system be switched over to a wet crushing step.

The underlying principle of the proposed system is to avoid using water at all in the diamond recovery process except when it cannot be avoided. Whereas in the past

diamond recovery plants have been designed for the worst case, in the new concept they would be designed for flexibility with the objective of using the minimum amount of water.

If the amount of wet slimes sent to the slimes pond were to be correspondingly reduced, then more expensive water recovery processes could be afforded.

3. Special dewatering screens could be employed to recover more water from the slimes fraction by removing grit and reducing the volume of material sent to the thickeners.

By removing grit from the "slimes" fraction a smaller pump will be needed e.g., 2 X 4 Warman may replace 6 X 4 Warman as only 30% of the weight of solids will now need to be removed to the thickener. An Austrian Lamella thickener is being tested for its degritting ability which looked promising.

4. Water Treatment in the Thickener

Innovative new flocculants and innovations in the way they are used has cut down flocculant costs from R800,000 in 1980 (would be R1.00 million in 1983 due to

inflation) to R200,000 actual 1983 budget. Flocculant purchases dropped form 289 tpa at their peak to 30 tpa.

This has been achieved by:

i) Prewashing the crushed ore with the worst quality water and sending it back to the dam without the use of the thickener.
ii) Appropriate flocculant selection. 5 years ago an Allied Colloids product was used, however today an improved flocculant has been found generally by using empirical test.
iii) Operators feel that a thorough study of the fundamental physics of high pH slimes from Kimberlites will lead to further improvements in flocculant selection, cost and performance.

ENVIRONMENTAL IMPACT

Dam Seepage

A seepage collection ditch is installed below the toe of the dam. The dam wall is provided with survey beacons and piezometers to detect any changes which could warn of danger in advance.

Tailings Dump Runoff

The runoff from the tailings appears to be clear but has a pH 9. It is collected and pumped back to the plant. About 960 m^3/year of water is collected from runoff from the 200 million tons of tailings.

Tailings Stabilization

It has been found to be possible to establish vegetation on the dump. "Star grass" which propagates by rizomes grows well and is suitable as cattle feed.

Several very effective flocculants have been tested in various parts of the world. For example polyethylene dioxide has worked on phosphate slimes but the required dosage is too expensive to be considered for Kimberlites so it has probably not been tested.

One observation of interest was made, is that addition of a small quantity of epsom salts together with the existing flocculant gives an immediate reaction and helps to settle the slimes. This was being examined to evaluate its potential economic usefulness.

Another way to enhance the settling of Kimberlite slimes is by adjusting the pH to 7 but this costs too much.

FLOCCULANT SELECTION

PREMIER

The fine particles of montmorillonite in Kimberlite with a high positive charge makes them difficult to settle.

Fresh and weathered Kimberlite circuits require different flocculants.

It has been found that there is a big difference in the zeta potential between fresh and aged "superfines" from Kimberlite.

An anionic flocculant made by Allied Colloids No. 156 & PDM3 is used. A Cyanamid flocculant A150 has also proven satisfactory. There are two flocculant addition points in the feed launder.

A typical dosage of Allied Colloids PDM3 and 156 mixed in a ratio of 3:1 is 5 ppm total. A typical overflow solids content of around 48 is achieved with these flocculants at the main plant.

Cyanamid A150 is used in the retreatment plant where aged Kimberlite is treated.

Flocculants in use at Premier Diamond Mine are supplied by:

CONCLUSIONS

1. It is generally concluded that diamond recovery operations from Kimberlites are in the early stages of learning how to use less water in their operations.

2. Because water has been inexpensive and available in the past there has been no major incentive to invest in water saving equipment or to use expensive reagents to help recover more water.

3. It is concluded that by investing more capital in a more flexible plant which can employ dry diamond concentrating processes during the dry months, and a wet plant during the rainy season, the amount of water can be dramatically reduced. However, water will have to be extremely expensive to justify the capital needed for such a plant.

OPERATION DELTA MANGANESE (PTY) LTD.
P. O. BOX 323
NELSPRUIT

TELEPHONE (01311) 25171

CONTACTS Anthony Dalrymple Technical Director
Lester Sherman Development Manager

INTRODUCTION

Delta Manganese treats Samancor manganese ore fines from Hotazel, Cape Province to produce up to 60 tpd electrolytic manganese flakes and powders. The process outlined below uses a calcine roast followed by sulfuric acid leaching to dissolve the ore, and then several stages of chemical precipitation to remove contaminant metals as hydroxides and sulfides, before electrowinning manganese metal from the purified solution.

In this process 712 m^3/d of effluents are generated of which 405 m^3/d is discharged directly to the river or municipal sewer while the remaining 307 m^3/d is pumped to an industrial water dam, the overflow from which is discharged to the river.

In addition, heavy metal impurities are precipitated and dumped in various dongas in the area as landfill.

Delta Manganese is an interesting example of a metallurgical operation where little or no concern for the environmental impact of their effluents was required in the past. Since South Africa is becoming increasingly conscious of water quality protection and the environment it is clear that steps will have to be taken in future to recover water for reuse at Delta Manganese and to find better ways of disposing of both liquid and solid residues.

LOCATION Nelspruit in the eastern Transvaal not far from the Mozambique border.

ORE Hotazel Manganese Ore fines from Samancor
13 mm x 0 in size

Mn_2O_3	45%	
Ca	4% max	
Fe(total)	11% typical	14% max

PLANT CAPACITY 60 t/d Manganese flake product

PROCESS

The ore is milled and dried (using hot offgases from the calcines) to minus 80 mesh.

Milled ore is calcined for 1 to 1½ hours at 750°C (max) (1000°C external temp) in tube calciners which are screw fed and fitted with spiral flights which provide 6" dams in the tube.

The calcines are electrically heated but fuel oil is added to the charge which breaks down into methane, CO and H_2 and reduces Mn_2O_3 to MnO. The tubes are fabricated from ALS 253MA stainless steel which is high in chrome and nickel. Fe^{2+} is measured in the kiln discharge. By the time all the iron is in the ferrous state, the manganese has also all been reduced to MnO.

After the reduction roast, the ore is leached at pH 6.2 and 120 g/l $(NH_4)_2SO_4$ in recycled spent electrolyte from the cellhouse. This dissolves the 11% Fe content.

The leach pulp is aerated and the pH raised to 6.8 which converts Fe^{2+} to Fe^{3+} and precipitates the iron. This is followed by addition of alum (to control silica) and a flocculant Magnafloc 351, and the slurry is then pumped to a thickener. Thickener underflow containing ferric hydroxide, silica and any undissolved ore is filtered on belt filters.

The filtrate is recycled to the thickener, and thickener overflow is next treated with $(NH_4)_2S$ to precipitate heavy metal sulfides including Ni, Co, Zn and some MnS.

The solution with precipitated metals is settled in a thickener. The sulfide underflow is pumped to a reactor where sulfuric acid is added which converts any manganese sulfide in the precipitate to H_2S and $MnSO_4$. The H_2S is reacted with ammonia to regenerate $(NH_4)_2S$ for use in the metal precipitation step. The residue after H_2SO_4 treatment of the sulfide precipitate is dried in a filter press and discarded with the belt filter cake in the municipal landfill and in dongas.

The thickener overflow solution is clarified by filtration employing two Funde disc filters and three Stellar Filters. It is essential to remove solids from the electrolyte. The solution is next dosed with SO_2 to modify the manganese from β to α crystals before being pumped to the cellhouse where manganese metal is electrolytically recovered on stainless steel cathodes by the following reaction:

$$MnSO_4 + 2e = Mn^{\circ} + SO_4^{=}$$
$$2H_2O = O_2 + 4H^+ + 4e$$

The electrolyte enters the cathode at 33g Mn/l and exits at 11 g Mn/l.
150 m^3/h of electrolyte is recycled back to the electrolyte tank at full manganese production of 3 tph.

The anodes are lead with 1% Ag. Diaphram cells are used because these limit the backmigration of H^+ to the cathode.

The cellhouse requires a 44MVA power source and takes 56kA @ 6.5V for 74 cells.

Manganese is physically knocked from the cathodes which are then taken to a plate treatment area where they are flexed, acid washed and rinsed before being recycled to the cells.

Sodium silicate is added to the electrolyte as a smoothing agent; the solution is made up once a day and the spent solution is purged prior to new solution being made up.

If the cellhouse stops due to a power outage the manganese goes back into solution which costs a minimum of R5000/hour, so a standby generator is installed.

EFFLUENT STREAM COMPOSITION AND DESTINY

Stream		Volume	Destiny	pH	TDS ppm	S/S ppm	Ca^{++} ppm	$SO_4^{=}$ ppm	Mg^{++} ppm	Na^{+} ppm	Mn ppm
1) Cathode Treatment	Na_2SO_4	14 m^3/d	River	9.5		50				1200	
2) Plate Wash	Acid	202 m^3/d	164 m^3/d to sewer 38 m^3/d to river	5.0		50	145	400	110	-	
3) Detergent Solution	detergent	5 m^3/d	Sewer			no data					
4) Metal Wash		88 m^3/d	River and BF wash	8.2		300	150	1140	180		290
5) Belt Filter Cloth Wash		75 m^3/d	Industrial Water Reservoir			100	216	5960	430		1520
6) Cell Frame & Diaphram Wash		144 m^3/d	Industrial Water Reservoir	3.3		350	450	1100	120		300
7) Cooling Tower Blowdown		56 m^3/d	Recycled		1200	140	350	420	240		90
8) Clarifilter Rinse		40 m^3/d	Recycle & River	5.5		no data					
9) Cellhouse Wash		(sporadic 88 m^3/d)	River	6.5		no data					
10) Calciner Cooler		5 m^3/d	Recycle	7.5		100	230	760	180		

GYPSUM SCALING

Most of the solutions in the plant are saturated with gypsum. Every dayshift a gang of 8 laborers plus one foreman work as a pipecleaning gang at a significant cost.

Delta Manganese are wary of using any gypsum scale inhibitors because its effect on the Cellhouse performance cannot be predicted.

ENVIRONMENTAL

The effluents from Delta Manganese are dumped into a small stream on the edge of Nelspruit which flows into the Crocodile River and then to the Komati River which flows through Mozambique to the sea.

Solid wastes are currently dumped at a municipal landfill which will be closed mid-1985 when a new municipal dump is opened 10 k from the townsite. RANDOL expects that sulfide metal precipitates and effluents containing ammonia would be harmful to the environment.

NATURE OF EFFLUENTS

All the effluents are rather similar and contain:

$(NH_4)_2SO_4$
$Ca\ SO_4$
$Mg\ SO_4$
$Mn\ SO_4$
$Co,\ Ni,\ Zn\ (SO_4)$

All effluents run less than 0.1 ppm heavy metals except three streams.

WATER SOURCE

All water used at Delta Manganese originates from the Crocodile River. Potable water is purchased from the municipality after flocculation, settling, clarification and chlorination. Industrial water is purchased after it has been flocculated and settled only.

WATER AND EFFLUENT MANAGEMENT PLAN

Phase I — The first phase of Delta Manganese water recycling plan is to bring all the effluent streams to the industrial water Dam where they will be commingled. About 60% of the present volume can be reused after settling out suspended solids.

Phase II It was planned to cut down on water usage in several possible ways:

1) Counter current plate washing
2) Cross current metal washing

Phase III Plate and metal wash solutions if treated with lime will precipitate all metals except Na, according to Delta tests. It was proposed to treat these streams with lime ahead of the industrial water dam. This stream would then be settled in a high rate thickener with u/f going to the belt filters and o/f going to the industrial water dam.

Of an expected flow of 574 m^3/d into the industrial water dam, Delta expects to use 561 m^3/d which leaves only 13 m^3/d to be bled to the river compared to the present 557 m^3/d discharge.

Phase IV The potential exists to recover manganese from the 574 m^3/d of effluents, and $(NH_4)_2SO_4$. A process scheme has been devised to put manganese back into the process and to concentrate the $(NH_4)_2SO_4$ for use as makeup to replace the ammonia and sulfate lost in the belt filter residue.

Delta was considering a MINTEK ion exchange process for recovering manganese at a low pH. The broadbrush water treatment process concept is as follows:

WATER TREATMENT CONCEPT

1. Reduce pH to 4 by H_2SO_4 addition

2. Recover Mn by IX

3. Adjust pH to 7 which makes the water non-corrosive, and drop out Fe^{3+}, Co, Ni, Mn and Al^{+3}.

4. Settle and send the overflow water to the industrial water dam

5. Water in excess of needs for industrial water, to be treated by a desalination process to recover $(NH_4)_2SO_4$ and H_2SO_4 which can be used to regenerate the resin and strip the recovererd manganese into a $(NH_4)_2SO_4$ solution to be added back to the electrolyte.

Experiments have been performed with commingled effluent solution and showed that lime addition to pH 8.2 achieves the following result:

	Raw Commingled Effluent	After pH Adjustment with Lime to pH 8.2
Suspended solids	250	6000 ppm
Mn	380	0
Na	120	140
Ca	340	1080
Mg	135	90
SO_4	1370	1450
pH	7	8.2
TDS	2500	2700

It was conceded that implementation of anything beyond Phase I is still a long way off.

DISCUSSION

1. In the electrolyte purification step, large settling tank capacity is required to remove the finely discarded sulfide precipitates. RANDOL believes that DAF or some modification of an HDS process could make this step easier and more compact.

2. For recovery of manganese, the followng idea may be simpler:

3. Recovery of manganese at low pH by IX in the presence of iron is unlikely to succeed.

4. Recovery of $(NH_4)_2SO_4$ and H_2SO_4 by EDR from the solution after precipitating metals is an area of research both at MINTEK and elsewhere, but no commercial process has been indicated yet.

5. Considering the problems experienced with gypsum sealing and clogging pipes, it is possible that this would justify either looking at sequestering or anti-scaling reagent addition or the use of seeded slurry R. O. treatment of recycle water to remove CaSO and drop the levels in the plant below saturation.

MINE BURNSIDE COLLIERY
P.O. BOX 222

Mr. Gideon Van Aswegen — Site Restoration Superintendent
Northfield Colliery
P. O. Box 222
Glencoe, Natal 2930

Telephone: (0341) 31137

LOCATION The worked out Burnside Colliery is located on the outskirts of the town Glencoe in Natal about one hour's drive Southeast of Newcastle.

CLIMATE Warm yearround with predominantly summer rainfall.

INTRODUCTION

The original Burnside Colliery operations were granted a closing certificate at least a decade ago before the need to comply with new environment protection regulations (Regulations 513-3 of 1982). The Dept. of the Environment has recently spent R1.5 million on the site to prevent pollution of the Buzi stream which had become contaminated to the extent of being unusable by farms downstream.

The later operations of the Burnside Colliery were incorporated in the Northfield Colliery operations of the Trans Natal Division of General Mining Company, now known as Gencor Ltd.

When the last Burnside Mine was shut down the site had to be restored to comply with current environment protection regulations.

Excerpt from paper by J.O. KEMPE (1983) :

(iii) Burnside Area - Northern Natal

A stream serving a farming community in the Burnside area in Northern Natal was being seriously polluted by underground water which surfaced against a dyke contact and by a small amount of seepage from an old waste dump bordering on the stream. It was decided to divert the stream from the problem area and construct an evaporation dam across the original stream to contain the polluted water. The diversion was 1 200 metres in length. To avoid erosion of the sandstone and soft shale exposed in the 6,5 metre wide channel graded at 1:400 it was necessary to construct four concrete lined stilling bays. The satisfactory effect of the completed project on the quality of the water in the stream is indicated in Table 9.

TABLE 9 Quality of Water at Burnside Stream Diversion Project

	Sampling Position	pH	Total dissolved solids (milligrams/litre)	Sulphates (as SO_4) (milligrams/litre)
1.	Stream above problem area	7,8	95	7
2.	Water surfacing at dyke contact	6,8	4 720	2 350
3.	After confluence of 1 and 2	6,7	3 625	1 450
4.	Same as in 3 after diversion complete and evaporation dam commissioned	8,0	250	15

(2) Government Mining Engineer

MEASURES ADOPTED

Old Burnside Operations

Restoration of the old Burnside Colliery site has been the responsibility of the Department of Environment.

The major problem appears to have been the siting of a coal refuse dump along the course of the Buzi River. The Department of the Environment has spent R1.5 million on diverting the stream to bypass the dump site. A dam has been constructed to retain and evaporate water draining from the dumpsite therby preventing it from reaching the stream.

New Burnside Operations

1. Demolition of all buildings and mine headgear on site. Removal of rubble and foundations to the dump.

2. Removal of scrap metal from mine scrapyard and restoration of the site to grazing land.

3. Diversion of drainage stream around the coal waste dump which was sited on the stream channel. Construction of an 80,000 m^3 dam to retain runoff water above the tailings pile. Water is allowed to escape at a controlled uniform rate from the dam so as not to erode the dump. Cost of dam and stream diversion: R100,000.

4. The fenced off shaft collar has been sealed with a 2 m thick concrete plug. Wood matpack mineprops underground were treated to prevent rotting so the mine could be reopened in future. A valved pipeline is inserted through the seal in the shaft collar to allow contaminated water to be released if necessary. The collar of the mineshaft has been raised above ground level to prevent drainage water from flowing into the cavity above the seal.

5. A second shaft entrance has also been sealed and fitted with a valved drainage pipe.

   Contaminated water can be released if necessary into the creek during times of flooding when it would be diluted and eventually transported to the sea.

6. The wasterock and reject coal dump was compacted to prevent rainfall penetration and also to seal out air. This extinguished the fires and allows water to runoff rather than penetrate the dump. Runoff water drains to bermed dams around the periphery of the dump.

7. The dump and shaft areas were fenced. The area around the dump and shaft was planted with grass.

8. Open pit excavations were filled in and available topsoil replaced and the area grassed.

9. Restoring the Burnside minesite was included in a combined budget for Burnside and Northfield of R3.0 mm (1982/3).

Conclusions

1. The principle of releasing contaminated minewater to streams during times of flooding appears to be sound where the streams lead ultimately to the sea, and where adequate dilution is provided by the floodwaters.

2. Shortage of topsoil prevented complete restoration of the open cast minesite area.

3. The minesite as originally abandoned included several brick buildings with corrugated iron roofs. These have since been gutted by looters leaving very unsightly building shells. This justifies the requirement that all buildings on abandoned minesites be demolished except where specific exclusions are granted on application motivated by specific uses for buildings to be left standing.

4. Compaction of the waste dump surface is effective at putting out fires in the dump which has been a major contributor to acidity.

5. The Burnside waste dump will always remain as a stark reminder of mining activity on the site. The dump had been sited on a streambed and had expanded right up to the property boundary which required removal of material to install berm dams for restoration. With foresight and planning in the layout of mines and wastepiles in the initial stages it would be possible to achieve less costly restoration on completion.

6. Gencor Ltd. has retained Mr. P. J. Buys, former General Manager of the mine, to be responsible for the mine restoration over a 3 year period.

   Employment of such a senior man for the task not only expedited the restoration program by allowing more rapid ad hoc decisions to be made, but also has provided an insight into the needs of site restoration which will be valuable in the planning and layout of new operations in future.

7. According to Mr. Hendrik J. Best of the Department of Water Affairs & the Environment, the restoration of Northfield and Burnside Collieries are exemplary of

how things should be done and these sites will serve as models for the South African coal mining industry.

8. Although water quality in the Buzi River was unacceptable due to pollution by minewater and dump drainage prior to restoration, data on water quality before and after was not available. No systematic monitoring program of surface and groundwater of the type required in the USA seems to have been carried out.

9. Despite extremely heavy rains on the night immediately prior to the visit, the berm dam impoundments contained only "very little" water, clearly far less than had flowed off the dump at Burnside. Water had both sunk into the ground and overflowed to banks of one berm dam thereby being lost to the stream. No groundwater monitoring has been required at the site.

10. Mr. P. J. Buys and Mr. G. van Aswegen both emphasize the need to consider post-operation restoration of the site at the initial planning stages of the mine.

11. A wasterock and reject coal dump design that would be less expensive to restore to fulfill the requirements of Regulation 513-3 of 1982 was suggested as follows:

    1) Construct clay berm dam impoundment around the site.
    2) Heap wasterock to no more than 15 ft. (5m).

    Once filled the dump can be smoothed off into a mound and compacted before being covered by the berm material and then a layer of topsoil for Kikuyu planting.

12. Grass (Kikuyu) has been planted on the restored minesties. Kikuyu (used in most South African domestic lawns) propagates by means of rizomes and is ideal for minesite restoration also on account of its hardiness. Most North American grasses for example are less suitable as they grow as individual plants from seed and such grasses will not fill in gaps except through seed propagation.

    At Burnside Kikuyu grass used for restoration planting was taken from as close as possible to the site to obtain plants already adapted to the acidic soil environment.

13. A dam constructed at the open pit restored site is said to contain acid water when allowed to stand.

Collar around old shaft which is now plugged.

Flood damage to runoff catchment ponds alongside compacted coal waste dump. Note incipient grass growth.

Effective drainage diversion around the Waste Pile

INTRODUCTION

In the 1950s Anglo American Corporation operated the largest electrodialysis plant in the world to treat minewater at Welkom. This operation shut down, because the volume of water that required desalination decreased to the extent that the plant was no longer needed.

Since EDR has been advocated as a candidate desalination process for neutralized acid mine drainage on the Witwatersrand, and since there are none installed for this purpose on a commercial scale, there was no option but to visit a commercial EDR plant installed in a different industry to get a feel for this type of process. Accordingly the EDR plant at Kriel power plant was informally visited in the company of the vendor who installed the unit.

MODEL OF EDR UNITS Aquamite 100, Two trains installed Kriel

SIZE OF EDR PLANT 6000 m^3/d

PURPOSE OF EDR PLANT

As a rougher desalting for boiler feed water ahead of an ion exchange demineralizer plant which became overloaded when feedwater quality deteriorated from 40 ppm to 300 ppm TDS. The water must be demineralized for use in the Kriel Power Plant boilers. The EDR plant was treating Vaaldam water with 300 ppm TDS to make feedwater for the existing ion exchange demineralizer with 40-60 ppm TDS.

DATE OF INSTALLATION 1983

DURATION FOR INSTALLATION

The EDR plant took 2 months to install from receipt of the order which is a truly remarkable achievement.

DESCRIPTION OF EDR PROCESS

Water is desalinated by removing cations and anions through ion exchange membranes on either side of a layer of water between the reversible anode and cathode of a cell. A description of the EDR process is provided in the chapter on desalination.

SALTS REMOVED

The main salts in the water treated by the Kriel EDR plant are SO_4^+, Ca^{++}, Mg^{++}, $SO_4^=$ and HCO_3^-.

PRETRETMENT

Feedwater is clarified and then filtered in sand filters ahead of the EDR plant which was inserted between the two existing stages of pretreatment at the power plant.

A 10 micron disposable paper cartridge filter is installed in the feed line to each train of EDR stacks.

EDR STACKS AND ARRANGEMENT

The Ionics EDR stacks employed have 500 cells per stack, each consisting of two membranes and a cathode and an anode plate. Each stack of 500 cells costs about $30,000 and can treat about 30 gpm. Each section of the plant employs 4 stacks in series.

REVERSAL CYCLE

Concentrate flow loops around continuously. Flow direction is reversed each cycle by automatically controlled flow reversal values. At each reversal a small amount of makeup water is added to the concentrate and demineralized product is withdrawn. The Kriel EDR plant operates on about a 30 minute reversal cycle because the feedwater has a relatively low TDS level.

DEGREE OF CONCENTRATION POSSIBLE

Concentration of TDS must not be allowed to build up too much. If the Langelier index exceeds 2.3, then acid is added to the system.

When $CaSO_4$ concentration exceeds 180% of saturation a sequestering agent is added to the concentrate stream. Sodium hexametaphosphate is added.

SCALE INHIBITION

$CaSO_4$ scale is inhibited by addition of Na hexametaphosphate. Calcium sulfate precipitation is a lime-controlled phenomenon. By recycling the flow and cell polarity it is possible not to give the crystals time to form. If some $CaSO_4$ crystals should happen to form this occurs against the membrane. The changing polarity and flow helps to move these partially formed crystals out of the system. EDR systems have been demonstrated working with $CaSO_4$ concentrates up to 400% of saturation.

At the Cathode conditions are alkaline and therefore more conducive to scale formation. Water flows over the cathode to provide a continuous electrode rinse.

At the anode conditions are acid and therefore not scaling. The anodes are rinsed intermittently to eliminate gas blanketing.

The concentrate continues flowing in a loop all the time. The reverse flow valves simply reverse the flow at the same time they allow a small amount of new water to enter the concentrate to make up for water lost to the product.

An empirical formula known as the Marshal Slusher formula can be used to predict scaling.

EARTHING SOLUTIONS

Solutions entering or leaving the EDR plant must be earthed. Stray currents would otherwise cause corrosion of the steel parts in the system. Each stack is earthed independently too.

MATERIALS OF CONSTRUCTION

Kriel

The stacks are held in place between two 1" thick plastic end pieces which are bolted tightly together between two 34mm steel framends which weigh 250 Kg apiece.

All pipes and valves are made of PVC.

WATER PRESSURE

Water is fed to the system at about 100 psi and a typical system water pressure is 60 psi.

CURRENT VOLTAGE

The current applied for EDR is 300 volts, DC.

PIPES AND PUMPS

All pipes are conventional plastic. Conventional centrifugal pumps are used.

CAPITAL COST

An EDR plant of this size costs around R3 million including the still building fitted with an overhead crane.

OPERATING COST

Operating costs for Escom units are considered confidential, but for feedwater with higher TDS, the vendors claim that operating costs run about R0.35/m^3. The major factor in operating cost is the cost of capital.

CLEANING AND MAINTENANCE

An EDR stack with 500 cells can be pulled apart for manual cleaning. The top electrode plate weighs 250 Kg and requires a crane to move. A 3t crane is installed in the roof of the Kriel EDR plant.

GENERAL APPEARANCE

The EDR plant at Kriel power plant is extremely clean and tidy. The desalination plant was relatively compact compared with what one would expect for a flow of this size.

COMMENT

Although EDR plants are claimed to be suitable for desalination of brackish water - and even seawater according to some accounts, this installation does not represent a true test because the feed water is relatively pure - only 300 ppm TDS. This is not typical of AMD water which is likely to run 3000-5000 ppm TDS.

Mr. Gideon Van Aswegen
Site Restoration Superintendent
Northfield Colliery
P. O. Box 222
Glencoe, Natal 2930

Telephone: (0341) 31137

LOCATION

The now exhausted Northfield Colliery is located in the outskirts of the town of Glencoe, about one hour's drive Southeast of Newcastle, Natal.

CLIMATE

Warm year round with predominantly summer rainfall.

INTRODUCTION

The Northfield Colliery ceased operation in June 1982 after operating continuously since 1917. Final year production was 45,000 tons per month plus 10,000 tons per month of wasterock which was dumped onto a culm pile.

Closure of the mine had to comply with a new environment protection regulation 513-3 of 1982, and the owners, Gencor Ltd. have spent R3.0 million on restoration of the 1000 hectare site including parts of the adjacent Burnside Colliery which were incorporated into the operation. Although restoration focuses on restoring the land as close as possible to its original contour and condition, preservation of water quality is a major factor that was taken into consideration.

REGULATORY AUTORITIES Department of the Environment
Pretoria
Telephone: (012) 268-402

MEASURES ADOPTED

1. The shaft headgear was dismantled and scrapped. The shafts were filled in.

2. Demolition of all buildings, storage bins, etc. not exempted by the Government Mining Engineer and the Department of the Environment.

3. Compaction of the top surface of the waste rock and reject coal dump to extinguish fires and allow rainwater to drain off rather than to penetrate the dump.

4. Construction of berms around the dump to retain drainage water. The berms also prevent surface water from draining into the dump and becoming contaminated. On the downgrade side of the dump the berms are constructed three deep.

5. Berm dumps prevent surface runoff water from entering or leaving the fine coal waste dam impoundment area. All berm dams are designed to hold runoff water from a 100 year rainfall.

6. Each dump and impoundment area is fenced off with 8 ft. fences and signboarded as a danger area.

7. All scrapiron and discarded equipment has been disposed of. (Either sold to a nearby steel mill or buried.)

8. Gradients of all disturbed land have been restored as close as possible to the original, and covered with topsoil.

9. Old aggregate pits on the property have been filled in and graded.

10. The berms and all restored areas have been planted with Kikuyu grass.

11. The Wasterock and reject coal dump is constructed with a significant slope (in the opposite direction to the slope of the ground. This grade allows water to runoff and drain from the dump surface and avoids ponding of precipitation.

CONCEPT FOR IMPROVED COAL WASTE DUMPS

Kikuyu Grass Can Grow on Coal Waste

Containment & Evaporation of Runoff

Revival of trees and note pumpkin seedling and grazing in foreground after compaction of Waste Dump and installation of berms.

CONCLUSIONS

1. Compaction of the dump surface to limit seepage of water into the dump as well as air to fuel the combustion results in greatly reduced SO_2 emission and hence less acid generation. The compacted dump at Northfield Colliery is evidence of this. Old gum trees that appeared to have been killed are now sprouting new leaves.

2. Kikuyu grass planted as cuttings and sod are growing very well on the berm embankments and surrounding areas. Grass has also been planted on the dump itself. In test areas planted one year ago, the dump is almost covered in grass which appears to grow even without additional topsoil covering the dump material.

   The use of acclimated grass plants from the same acid environment is said to make a big difference to its survival in a relatively harsh environment.

   Pumpkins have been planted on restored waste areas as a test because it is reputed that pumpkins thrive in acid soil.

3. The older evaporation ponds which were much more extensive than the current berm ponds, are now almost completely grass covered, and apparently lifeless trees are coming to life again. By keeping runoff water from draining into the area, the need for evaporation pond area has been cut down significantly.

4. The restoration efforts at the old Northfield minesite have been encouraging, and it is clear that the areas affected by highly acidic water can be restored or at least greatly improved. Acid generation from wasterock and reject coal dumps seems in this case to be controllable. Only the smallest signs of combustion were observed on the dump, which hopefully will be eliminated altogether once grass cover is established over the whole dump.

5. It is not known to what extent the 60 mm (2.3 inches) of rain that fell on the dump within 72 hours preceding the visit contributed to extinguishing the dump fire.

6. No groundwater monitoring program was mentioned or in evidence at the site. Considering the extent of rainfall over the previous three days the level of water in the berm dams was surprisingly low. No quantitative data was available on groundwater quality effects. The dump is located adjacent to a clay deposit mined by COROBRICK and it is possible that the clay deposit extends beneath the waste dump.

7. Boreholes have been drilled into the underground workings. Water although at neutral pH 7 has a high salt content. The municipality of Coligny draws water from the Northfield underground workings when there is adequate fresh water in the dams with which to blend it. Farmers are also said to have tapped water from the Northfield underground workings and it was also stated that although at a neutral pH the water is too high in salt content for most agricultural uses.

8. Based on the operator's experiences in restoration of the Northfield Colliery it was stated that new operations would be planned so that waste dumps would not exceed 15 ft. in height. These would be progressively restored as they became filled. In this way combustion would be controlled, acid runoff would be reduced and ultimate contours of the dump area would blend into the natural topography.

9. Details gathered during the visit on 13 December 1983 were qualitative in nature. It remains to gather quantitative data on the following:

   - Water quality monitoring program (if any)
   - Water quality before/after restoration
   - Plan of affected areas
   - Breakdown of restoration costs
   - Analysis of how a new mine would be planned so as to minimize restoration costs
   - Regulation 513-3 of 1982 regulating mine closure
   - List of regulations affecting water quality at a coal mine
   - Climatic constraints
   - Water quality of underground minewater and discussion
   - Diagram of area showing affected areas
   - List of regulatory authorities and names, addresses and phone numbers of individuals concerned
   - Names of consultants involved (if any)

QUESTIONS

1. Breakdown of expenditures on restoration of the sites at Burnside and Northfield Collieries.

2. Which items and what cost can be assigned to measures that improve ro preserve water quality?

Berm keeps runoff water inside the Waste Area to evaporate. Note natural marsh.

Note Revival of tree after Waste Pile was compacted and fires extinguished.

3. Details of any monitoring program to measure water quality before restoration and after restoration.

4. Government Departments and names of individuals involved or consulted in connection with the restoration plan. Names and addresses, please.

5. Names of independent consulting firms or contractors employed to assist in the environmental aspects of the restoration plans.

6. Where mineshaft openings are sealed and fitted with a valved pipe outlet to bleed minewater:
   1) Who specifically will monitor the need to bleed minewater?
   2) Who will make decisions as to bleeding minewater?
   3) Who will open/close the valves?

7. When is it anticipated that a mine closing certificate will be granted

8. Full name of the Gencor Division that controls Northfield and Burnside Collieries, i.e., Trans Natal ...

9. Size of the dumps. Surface area. Size of the berm dams (surface area and wall height)

10. Measures to remove silt from berm dams as they fill up?

11. Other ongoing maintenance items.
